Reservoir of moisture

Each bath with Alpha Keri® Therapeutic Bath Oil is a reservoir of moisture for dry skin. The addition of Alpha Keri in the bath helps skin store moisture for days. And feel soft, smooth, and supple in minutes. (Between baths, a single application of Keri® Lotion instantly restores moisture to dry skin for hours.)

Alpha Keri®
Therapeutic Bath Oil

helps skin keep in touch with moisture

See PDR for complete product information.

For effective and individualized control of acne....

Prescribe the only benzoyl peroxide acne medication available in cover-up lotions....

LOROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

(benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%) (benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%, hydrocortisone ½%)

- Contains the proved synergistic bactericidal combination of benzoyl peroxide and chlorhydroxyquinoline (300% greater antibacterial activity[1]) — which topically reduces C. Acnes *within* comedones[2]
- LOROXIDE-HC® effectively treats papular, pustular and cystic acne[3] — a favorable response has been reported in 75% of patients in as short a period as two weeks[4]
- Ideal therapy providing "all day," penetrating antimicrobial activity with controlled drying and desquamation — at school, work or play.
- No sun-sensitizing properties — no need to restrict your patient's outdoor activities or eliminate the known benefits of natural UV exposure.
- *The only* adjustable tint-intensity benzoyl peroxide lotions available.
- Replaces and helps to prevent abuse with over-the-counter cosmetics.
- For *day-long control* of all grades of acne vulgaris.
- Lesion-masking base helps to eliminate the..."natural but distorted feelings that other people perceive him as 'acne with a person attached rather than as a person who happens to have acne.'"

Dermik Color Blender™

EXCLUSIVE!

Dermik

Dermik Laboratories, Inc.
Fort Washington, Pa. U.S.A. 19034

OROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

DESCRIPTION: Loroxide Acne Lotion contains (as dispensed) benzoyl peroxide 5.5%, and chlorhydroxyquinoline 0.25%; incorporated in a water washable lotion consisting of purified water, propylene glycol, hydroxyethylcellulose, caramel color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, silica, kaolin, talc and titanium dioxide, with "Dermik Color Blender™" supplied separately.

Loroxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.5% and chlorhydroxyquinoline 0.25% incorporated in a lotion identical to Loroxide Lotion (see above).

Actions: Provides keratolytic, peeling and drying action.

Indications: An aid in the treatment of acne and oily skin.

Contraindications: This product is contraindicated for use by patients having known hypersensitivity to hydrocortisone, benzoyl peroxide, chlorhydroxyquinoline or any other component of this preparation. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia.

Warning — Usage in Pregnancy: Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established. Therefore, they should not be used extensively, or in large amounts or for prolonged periods of time on pregnant patients.

Precautions: For external use only. Keep away from eyes. If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Do not add any other medicaments or substances to this lotion unless specifically directed by physician to do so. Patients should be observed carefully for possible local irritation or sensitization during long-term topical therapy. Apply with caution on neck and/or other sensitive areas. There may be a slight, transitory stinging or burning sensation on initial application which invariably disappears on continued use. Ultraviolet and cold quartz light should be employed in lesser amounts, as this lotion is keratolytic and drying. Harsh, abrasive cleansers should not be used simultaneously with this lotion. Colored or dyed garments may be bleached by the oxidizing action of benzoyl peroxide. Chlorhydroxyquinoline may cause temporary light-yellowish skin staining in rare cases. Keep out of the reach of children.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneiform eruptions, and hypopigmentation. The sensitizing potential of benzoyl peroxide and chlorhydroxyquinoline are low, but they can, on occasion, produce allergic reaction. Occurrence of excessive redness or peeling indicates that the amount and frequency of application should be reduced.

Directions: Shake well before using. Apply a small quantity to affected areas with light massaging 1 to 3 times daily, or in accordance with the physician's directions.

(Important information directed to the Pharmacist: At time of dispensing, add contents of vial* to the bottle. Shake well and/or stir with a glass rod to insure a uniform dispersion. Place expiration date of three (3) months on bottle label.)

*"Benzie-Pak" vials contain a mixture of benzoyl peroxide 35% and calcium phosphate 65%.

Net weight of each vial is 3.8 grams.

How Supplied: Bottles, 25 Gm.

Caution: Federal law prohibits dispensing without prescription.

a completely dissolved hydrocortisone for optimal cutaneous penetration with a rapid release vehicle for maximum hydrocortisone effectiveness

nutracort® Gel

(1.0% Hydrocortisone Gel)

SCRIPTION: Nutracort* Gel 1.0% provides 1.0% drocortisone in a non-aqueous clear gel base ntaining propylene glycol, alcohol 22% (w/w), droxypropyl cellulose, and citric acid. NTRAINDICATIONS: In viral diseases of the skin h as varicella and vaccinia and in patients with a ory of hypersensitivity to any component. Not for thalmic use. Topical steroids should not be used n circulation is markedly impaired. PRECAUTIONS: itation develops, discontinue and institute opriate therapy. In presence of infection, use of opriate antifungal or antibacterial agents should be tuted. If a favorable response is not obtained mptly, discontinue until the infection has been equately controlled. Suitable precautions should be en against increased systemic absorption which may r if extensive areas are treated or if the occlusive ue is used. Should not be used extensively, amounts, or for prolonged periods in pregnancy.

ADVERSE REACTIONS: Burning sensation, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation have been reported with or without occlusive dressings. DOSAGE: Apply to affected areas 3 to 4 times daily. HOW SUPPLIED: Nutracort® Gel (1.0% hydrocortisone gel) is available in a 60 gram tube. Nutracort® Lotion is available in 0.25%, 0.5% and 1.0% strengths, 2 oz. and 4 oz. bottles Nutracort® Cream available in 0.25%, 0.5% and 1.0% strengths, 2 oz. and 4 oz. jars. Nutracort® Cream 1.0% also available in 1 lb. jars.

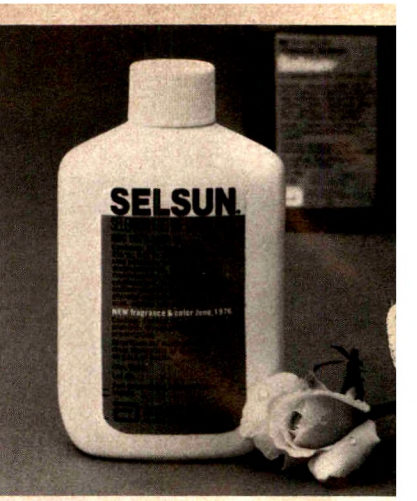
SUBSCRIPTION RATES: The yearly rate of the ARCHIVES OF DERMATOLOGY is as follows: United States and US Possessions, one year, $18; two years, $28; all other countries, one year, $28; two years, $38. Special yearly price to residents, interns and medical students in the United States and US Possessions, $9.

THE ARCHIVES OF DERMATOLOGY is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.



Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reaction should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 122 E 42nd St, New York, NY 10017, Area Code 212-867-6640.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

announcing BETADINE® microbicidal bath concentrate

to disinfect bath water before and during use

Effectiveness of disinfection demonstrated in test studies

Cultures of bath water were taken at specified intervals in 36 cases* before and during the immersion of a test subject. Bath water was recultured after adding BETADINE Microbicidal Bath Concentrate, and after the removal of the test subject.

Little contamination of bath water was seen prior to subject's immersion. High degree of contamination of bath water occurred one minute after subject's immersion (without use of BETADINE Microbicidal Bath Concentrate) regardless of the condition of the subject. No contamination of bath water could be seen in virtually all cases two minutes after the addition of BETADINE Microbicidal Bath Concentrate, while the subject remained in the tub and after subject's removal.

Test subjects in these studies presented various diagnoses, including psoriasis, neurodermatitis, bullous pemphigoid, stasis ulcers, contact dermatitis, burns, decubitus ulcers, diabetic gangrene, osteoarthritis, and

Wide area of use

BETADINE Microbicidal Bath Concentrate may be particularly useful in the disinfection of bath water whenever bathtub use is desired, as in hospitals, where persons suffering from bacterial and mycotic skin infections could contaminate the water. It can be used to help prevent contamination of bath water used by persons who are debilitated either through age, disease, or both, and who (due to their condition) are most often recommended baths rather than showers. It may be used to disinfect bath water before and during bathing of persons to avoid bacterial contamination of water in the bath.

Purdue Frederick

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author, (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

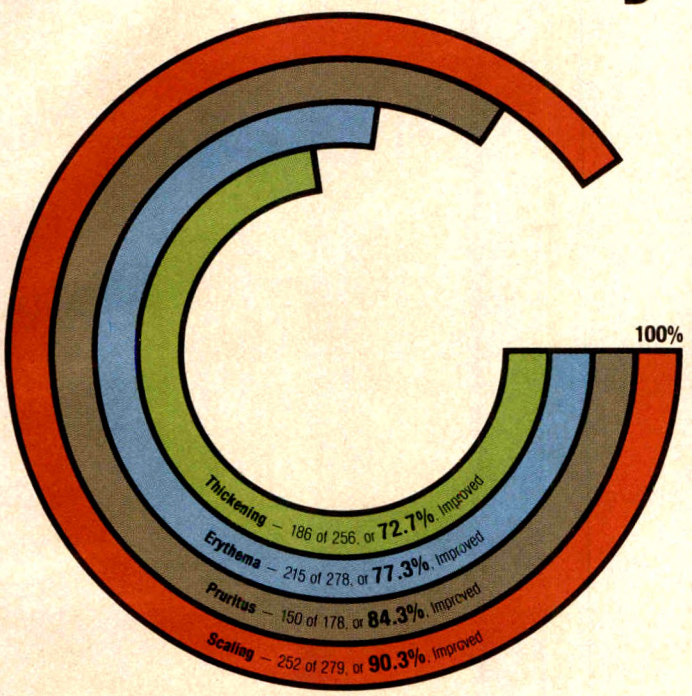
Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

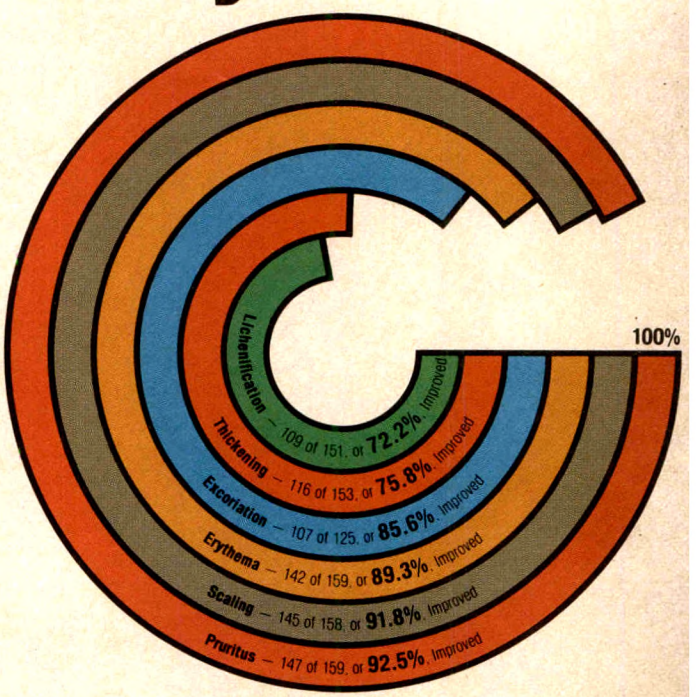
Inflammatory manifestations of psoriasis and atopic dermatitis...

Effectiveness demonstrated in only 8 days*



Psoriasis

In a study of 279 psoriatic patients



Atopic Dermatitis

In a study of 162 atopic dermatitis patients

Cordran® (Flurandrenolide)

Description: Cordran® (flurandrenolide, Dista) is a potent corticosteroid intended for topical use. **Actions:** Cordran is primarily effective because of its anti-inflammatory, antipruritic, and vasoconstrictive actions. **Indications:** For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. **Contraindications:** Topical corticosteroids are contraindicated in vaccinia and varicella and in patients with a history of hypersensitivity to any of their components. **Precautions:** If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, an appropriate antifungal or antibacterial agent should be used. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, there is a possibility of increased systemic absorption of the corticosteroid, and suitable precautions should be taken. Although topical corticosteroids have not been reported to have an adverse effect on pregnancy, the safety of their use on pregnant women has not been absolutely established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time on pregnant patients. These products are not for ophthalmic use. **Adverse Reactions:** The following local adverse reactions have been reported with topical corticosteroid formulations: acneform eruptions, burning, dryness, folliculitis, hypertrichosis, hypopigmentation, irritation, itching. The following may occur more frequently with occlusive dressings: maceration of the skin, miliaria, secondary infection, skin atrophy, striae. **Administration and Dosage:** For moist lesions, a small quantity of the cream or lotion should be rubbed gently into the affected areas two or three times a day. For dry, scaly lesions, the ointment is applied as a thin film to affected areas two or three times daily. [111875]

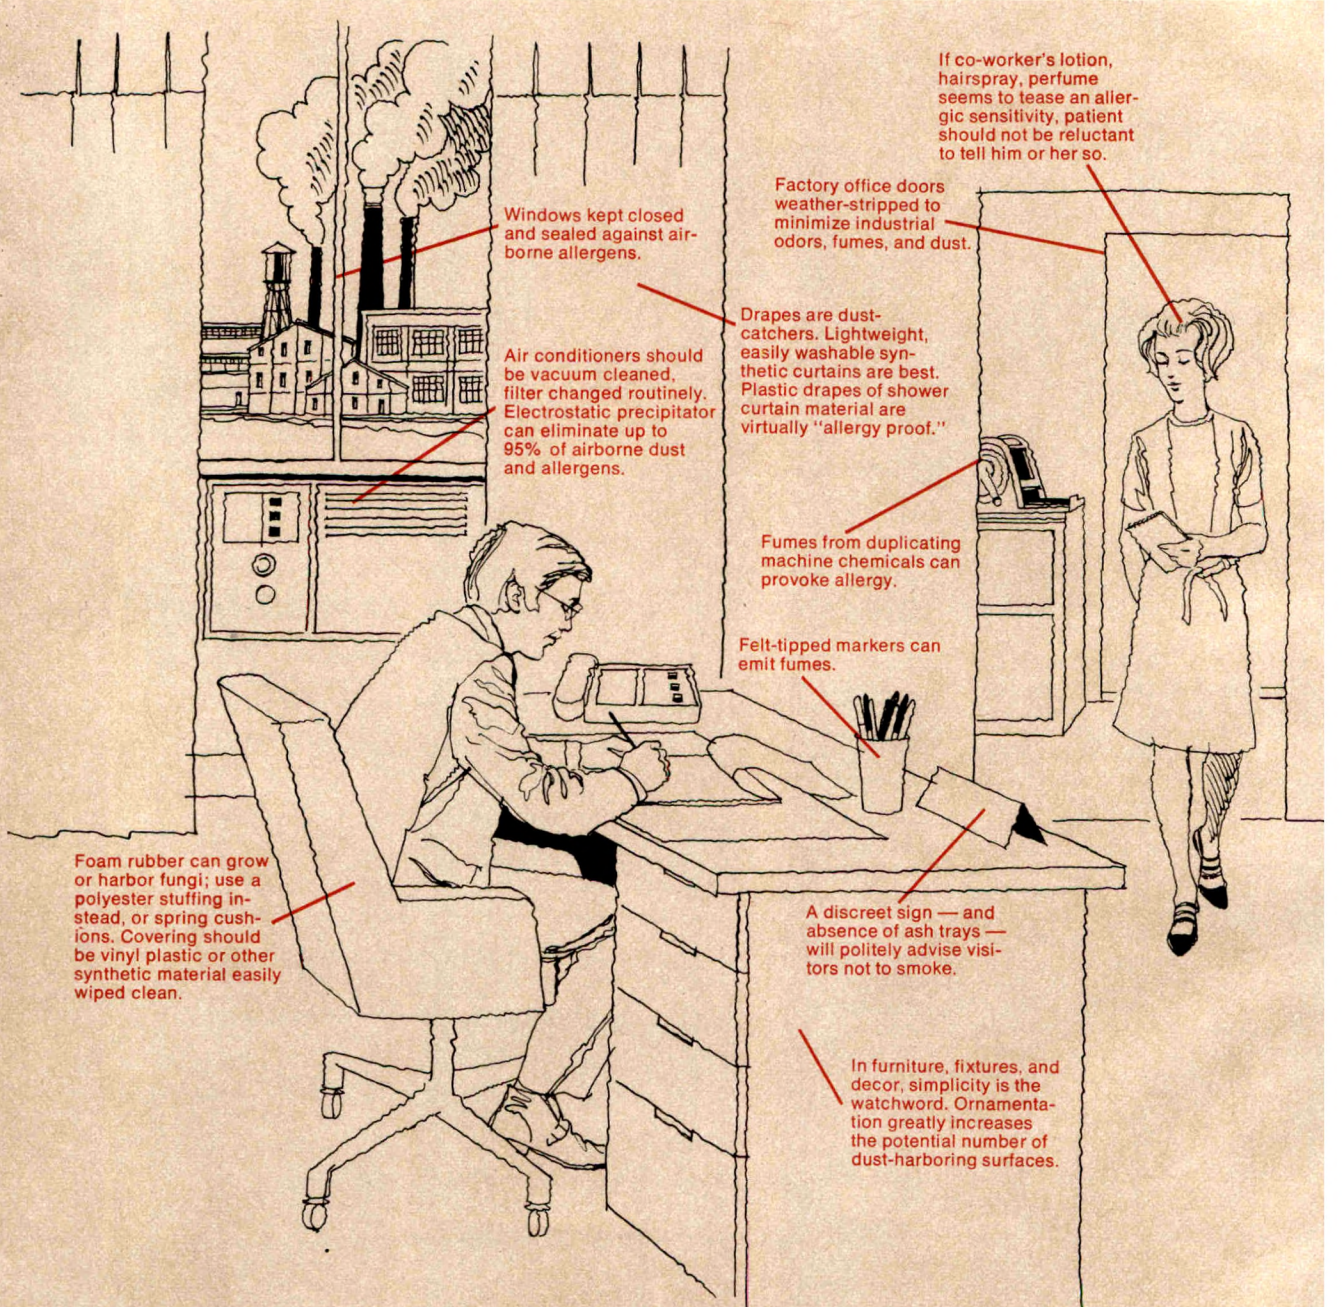
Efficacy is its strength

Ways to help allergy patients avoid "a bad day at the office"

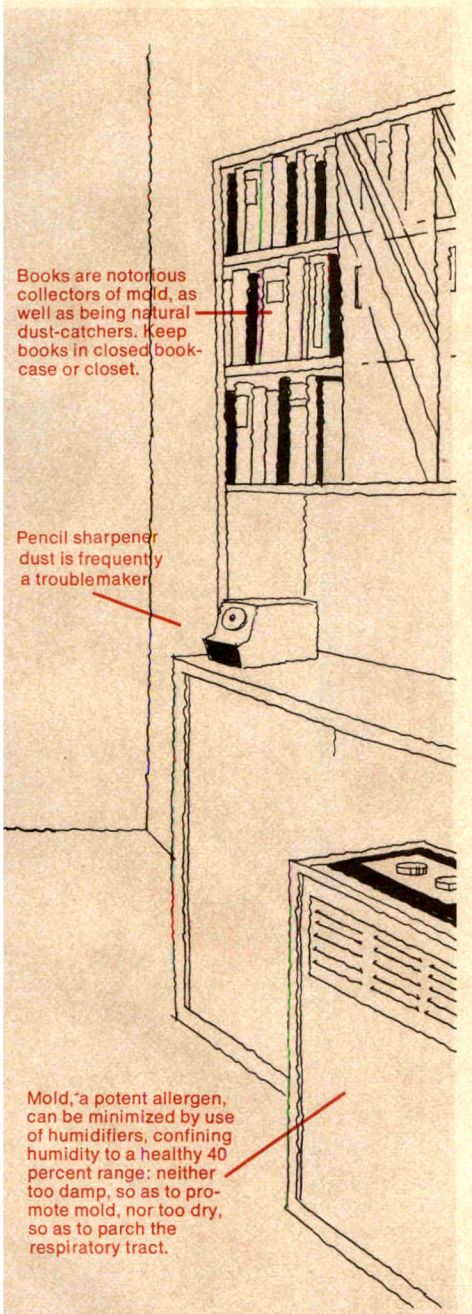
Your allergy patients who are offic workers may spend a quarter of thei adult life in a hostile environment - from an allergen standpoint. Here ar suggestions that might, with the hel of an understanding employer, lesse the allergic burden.



All measures to minimize exposure can be helpful. Still, allergic symptoms may occur and an antihistamine will be needed to bring these reactions under control. Dimetane Extentabs keep working for 10-12 hours, are economical, and are likely to produce good results in stubborn as well as routine cases, usually without drowsiness or overstimulation.

DIMETANE Extentabs®

(BROMPHENIRAMINE MALEATE,NF 8 mg. and 12 mg.)



Indications: Perennial and seasonal allergic rhinitis; vasomotor rhinitis; allergic conjunctivitis due to inhalant allergens and foods; mild, uncomplicated allergic skin manifestations of urticaria and angioedema; amelioration of allergic reactions to blood or plasma; dermatographism; as therapy for anaphylactic reactions *adjunctive* to epinephrine and other standard measures after the acute manifestations have been controlled. **Contraindications:** *Use in Newborn or Premature Infants.* This drug should **not** be used in newborn or premature infants. *Use in Nursing Mothers.* Because of the higher risk of antihistamines for infants generally and for newborns and prematures in particular, antihistamine therapy is contraindicated in nursing mothers. *Use in Lower Respiratory Disease.* Antihistamines should NOT be used to treat lower respiratory tract symptoms including asthma. Antihistamines are also contraindicated in the following conditions: hypersensitivity to brompheniramine maleate and other antihistamines of similar chemical structure; monoamine oxidase inhibitor therapy (see Drug Interaction section). **Warnings:** Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma; stenosing peptic ulcer; pyloroduodenal obstruction; symptomatic prostatic hypertrophy; bladder neck obstruction. *Use in Children.* In infants and children, especially, antihistamines in **overdosage** may cause hallucinations, convulsions, or death. As in adults, antihistamines may diminish mental alertness in children. In the young child, particularly, they may produce excitation. *Use in Pregnancy.* Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus. *Use with CNS Depressants.* Dimetane has additive effects with alcohol and other CNS depressants (hypnotics, sedatives, tranquilizers, etc.). *Use in Activities Requiring Mental Alertness.* Patients should be warned about engaging in activities requiring mental alertness, such as driving a car or operating appliances, machinery, etc. *Use in the Elderly (approximately 60 years or older).* Antihistamines are more likely to cause dizziness, sedation, and hypotension in elderly patients. **Precautions:** As with other antihistamines, Dimetane has an atropine-like action and, therefore, should be used with caution in patients with: history of bronchial asthma; increased intraocular pressure; hyperthyroidism; cardiovascular disease; hypertension. **Drug Interactions:** MAO inhibitors prolong and intensify the anticholinergic (drying) effects of antihistamines. **Adverse Reactions:** The most frequent adverse reactions are italicized: *General:* Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose, and throat. *Cardiovascular System:* Hypotension, headache, palpitations, tachycardia, extrasystoles. *Hematologic System:* Hemolytic anemia, thrombocytopenia, agranulocytosis. *Nervous System: Sedation, sleepiness, dizziness, disturbed coordination,* fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesias, blurred vision, diplopia, vertigo, tinnitus, acute labyrinthitis, hysteria, neuritis, convulsions. *G.I. System: Epigastric distress,* anorexia, nausea, vomiting, diarrhea, constipation. *G.U. System:* Urinary frequency, difficult urination, urinary retention, early menses. *Respiratory System: Thickening of bronchial secretions,* tightness of chest and wheezing, nasal stuffiness. **Overdosage:** Antihistamine overdosage reactions may vary from central nervous system depression to stimulation. Stimulation is particularly likely in children. Atropine-like signs and symptoms – dry mouth; fixed, dilated pupils; flushing; and gastrointestinal symptoms may also occur. *If vomiting has not occurred spontaneously,* the patient should be induced to vomit. This is best done by having him drink a glass of water or milk after which he should be made to gag. Precautions against aspiration must be taken, especially in infants and children. *If vomiting is unsuccessful,* gastric lavage is indicated within 3 hours after ingestion and even later if large amounts of milk or cream were given beforehand. Isotonic and ½ isotonic saline is the lavage solution of choice. *Saline cathartics,* as milk of magnesia, by osmosis draw water into the bowel and therefore, are valuable for their action in rapid dilution of bowel content. *Stimulants* should **not** be used. Vasopressors may be used to treat hypotension. **Dosage and Administration:** DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO THE NEEDS AND THE RESPONSE OF THE PATIENTS. *Adults:* One to two 4 mg tablets three or four times a day. One Extentab (8 or 12 mg) every eight to twelve hours or twice daily. Two to four teaspoonfuls of elixir three or four times a day. *Children over six.* One 4 mg tablet three or four times a day. One Extentab (8 or 12 mg) every twelve hours. One or two teaspoonfuls of elixir three or four times a day. *Children under six.* 0.5 mg of brompheniramine maleate per kg of body weight per 24 hours, or 15 mg per M^2 per 24 hours, divided into 3-4 doses.

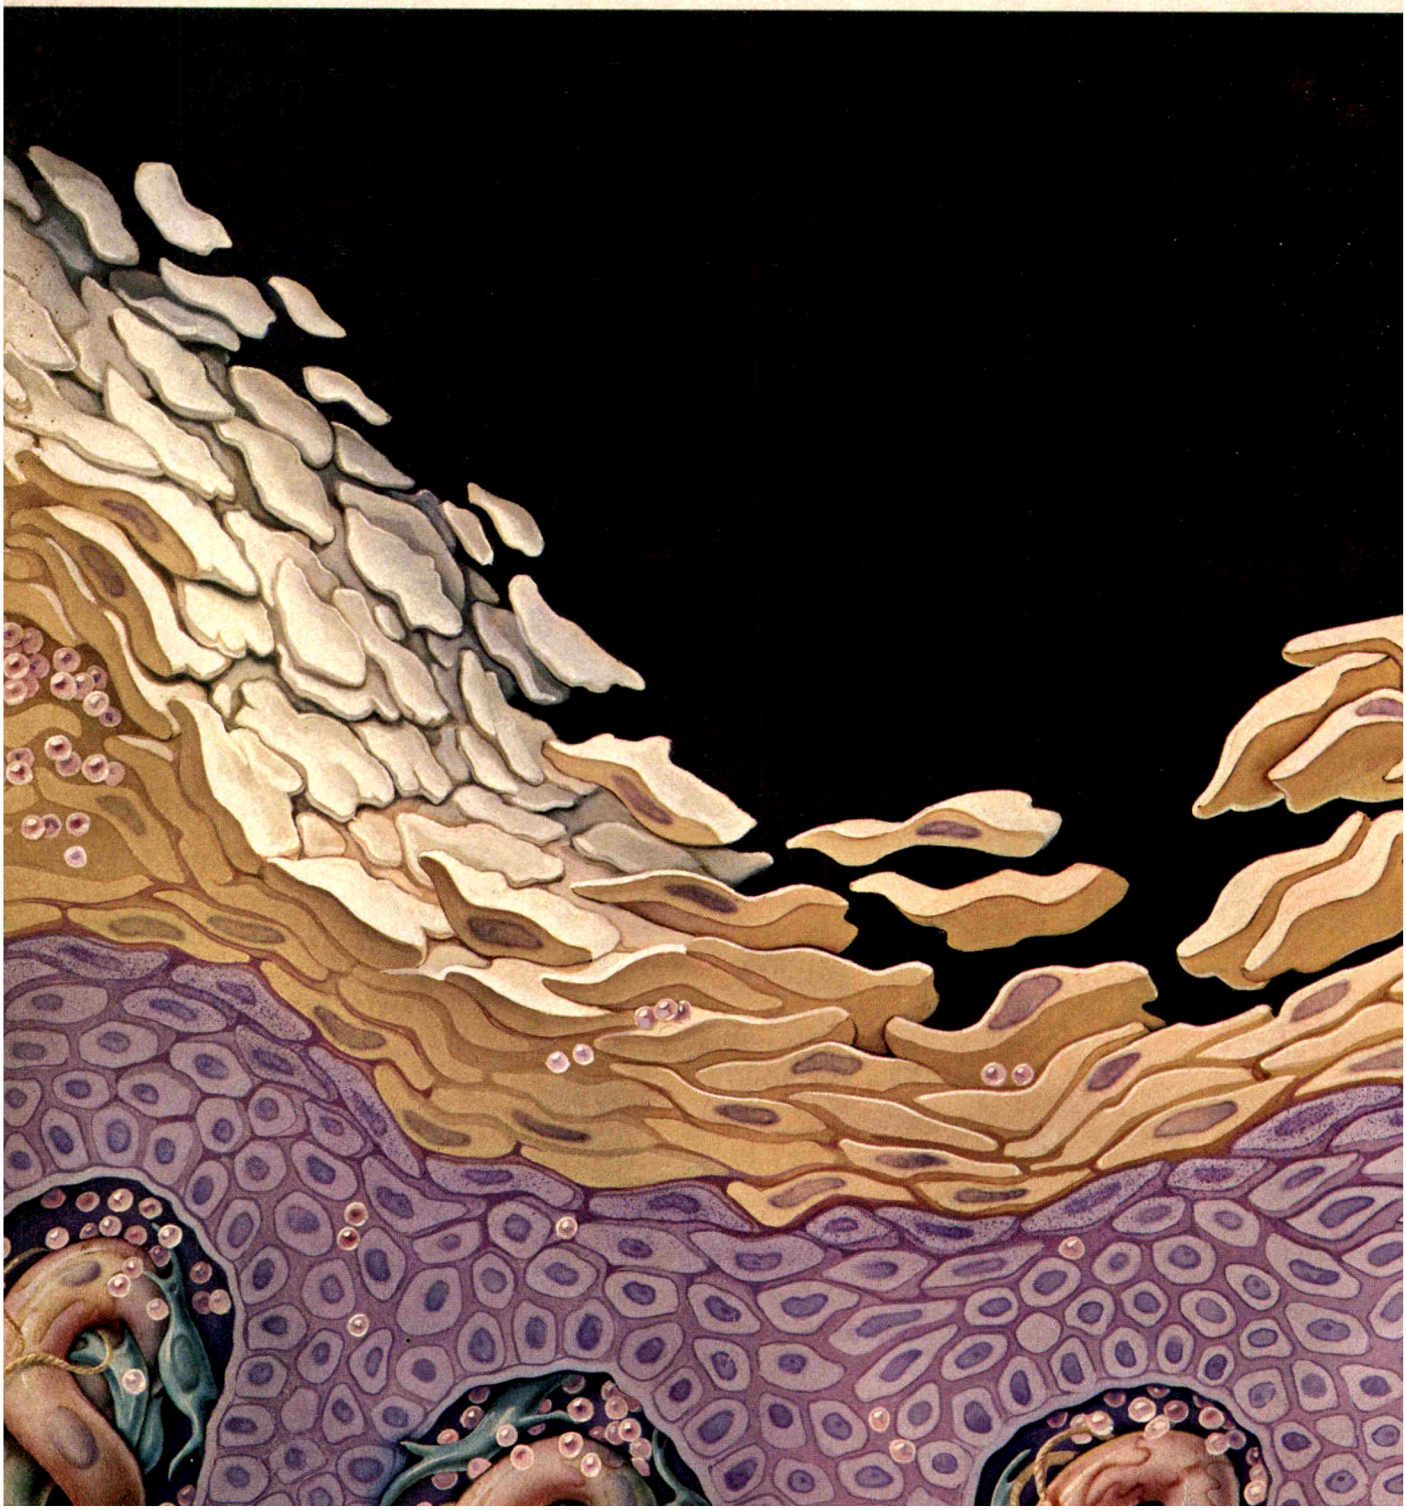
PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word ca
make an afflicted patient cringe. And,
because of the capricious, unpredictab
nature of the disease, the patient rarely
knows where or when it will recur.

Obviously, the goal is control. And,
though varied treatment modalities are
available today, none offers universal



efficacy for all patients, all of the time.

Yet, very often a highly effective topical steroid, like Lidex, (fluocinonide) can help stabilize psoriasis.

Lidex. A highly effective topical steroid with anti-inflammatory, vasoconstrictive, antipruritic actions.

100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

...safe for your patients to use, ...effective and less traumatic than cryosurgery or curettage[1]

Pet remedies for warts are almost as common as warts themselves. However, one specific formulation has again clinically proven its value.

R. B. Rees reported, *"My favorite wart remedy is . . . equal parts of salicylic acid and lactic acid in four parts of flexible collodion (Duofilm)".*[2]

Bunney and associates find the Duofilm formula, used at home, at least as effective as, and less traumatic than, cryotherapy and curettage.[1]

Arndt[3], in a double-blind controlled study of patients with multiple warts, confirmed Bunney's findings.

Duofilm is safe and simple to use. Special patient instruction pads and supplies of Duofilm for your treatment table are available on request.

Duofilm®

(Salicylic Acid, USP, 16.7% and Lactic Acid, USP, 16.7% in Flexible Collodion, USP)

for warts

Composition: Salicylic Acid, USP, 16.7% and Lactic Acid, USP, 16.7% in Flexible Collodion, USP.

Indications: DUOFILM is indicated as a keratolytic agent for the removal of benign epithelial tumors such as common warts.

Dosage and Administration: Prior to the application of DUOFILM, soak the affected area in hot water for at least five minutes. Dry thoroughly with a clean towel.

Apply DUOFILM directly to the wart using the plastic applicator. Each drop should be permitted to dry before re-application of the liquid. Care should be taken to see that DUOFILM is not applied to the surrounding skin. A Band-Aid® or similar bandage should then be applied lightly.

Treatment should take place once daily and continue as directed by physician.

Contraindications: Diabetics or patients with impaired blood circulation should not use DUOFILM. Do not use on moles, birthmarks or unusual warts with hair growing from them.

Precautions: For external use only.

DUOFILM is highly flammable and should be kept away from fire or flame. Keep bottle tightly capped when not in use. Store at controlled room temperature.

If spilled on mucous membranes or in eyes, flush with water, remove precipitated collodion, and flush with water for an additional 15 minutes.

Keep this and all medication out of the reach of children.

How Supplied: DUOFILM is available in ½ oz. bottles with plastic applicators.

Caution: Federal law prohibits dispensing without a prescription.

new LactiCare® Lotion

A genuine breakthrough in the management of dry skin.

More physiologic: LactiCare's unique formula restores humectants which occur naturally in normal healthy skin.

Prolonged protection that won't easily wash away: Unlike most humectants which easily may be rinsed away, lactic acid is adsorbed onto the cells of the stratum corneum and remains there to improve their water-retention ability, even after extended immersion in water.

Better moisture-binding ability: Both of the major humectants in LactiCare have been shown superior to the most commonly-used hygroscopic agents in their ability to absorb moisture and supply it to the stratum corneum.[1]

Greater economy: LactiCare is a highly concentrated lotion with a pleasant, thick creamy consistency. It should be used sparingly and less often than ordinary lotions. Even all-over body use costs only pennies a day.

Formula Lactic Acid USP 5.0%
Na-PCA 2.5%
in an oil-in-water lotion base containing: purified water, mineral oil, isopropyl palmitate, coceth-6, sodium hydroxide, glyceryl stearate, myristyl lactate, cetyl alcohol, carbomer-940, imidazolidinyl urea, fragrance, dehydroacetic acid.

Please see LactiCare file card for full prescribing information.

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

*Orentreich, N.: A clinical evaluation of two shampoos in the treatment of seborrheic dermatitis, J. Soc. Cosmet. Chem. 23:189 (March 3) 1972.

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

Patients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—particularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimple

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

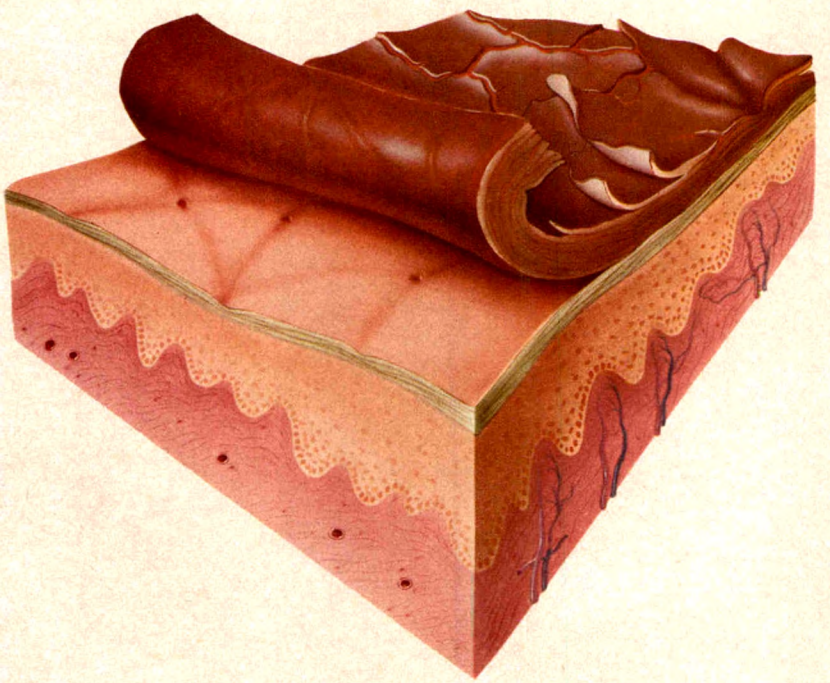
Get down to the level of normal skin.

Remove hyperkeratotic build up safely and effectively.



Keralyt® Gel is clear, and easy to apply. Keralyt Gel's mechanism of action is believed to be its ability to dissolve the intracellular material that binds the cells of the stratum corneum, thus aiding the simple, safe removal of excessive hyperkeratotic skin.

Keralyt's keratolytic action is an important preliminary to other topical agents. After the hyperkeratotic barrier is removed, tar, steroids, and other therapy can function with less impediment.

Keralyt® GEL

6% salicylic acid in a gel containing propylene glycol (60%), ethyl alcohol (19.4%), hydroxypropyl cellulose and water.
Please see full prescribing information.

©1977, W.P. Inc.

Available only on your prescription.

Keralyt® GEL

NDC-0072-6500-01

Rx CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

CONTENTS: 6% salicylic acid in a gel containing propylene glycol (60%), ethyl alcohol (19.4%), hydroxypropyl cellulose and water.

ACTION AND USES:
For Dermatological Use: Keralyt is a topical aid in the removal of excessive keratin in hyperkeratotic skin disorders, including the various ichthyoses (vulgaris, sex-linked and lamellar), keratosis palmaris and plantaris, keratosis pilaris, pityriasis rubra pilaris, psoriasis (including body, scalp, and palms and soles). Keralyt has been reported as helpful as adjunctive therapy for fungal infections.

For Podiatric Use: Keralyt is a topical aid in the removal of excessive keratin in dorsal and plantar hyperkeratotic lesions. Keralyt has been reported as helpful as adjunctive therapy for verruca plantaris.

DIRECTIONS FOR USE: The preferable method of use is to apply thoroughly to the affected area and place under occlusion at night. The skin should be hydrated for at least five minutes prior to application. The medication is washed off in the morning, and if excessive drying and/or irritation is observed, a bland cream or lotion may be applied. Once clearing is apparent, the occasional use of Keralyt will usually maintain the remission. In those areas where occlusion is difficult or impossible, application may be made more frequently, and hydration by wet packs or baths prior to application apparently enhances the effect. Unless hands are being treated, rinse hands thoroughly following application.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Keralyt.

PRECAUTIONS: In view of the salicylic acid content, use in children under 12 years of age should be limited to no more than one tube (1 oz.) in 24 hours. Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medications out of reach of children.

HOW SUPPLIED: Plastic tubes 1 oz. (24.8 gm.)

WESTWOOD PHARMACEUTICALS INC.
Buffalo, New York 14213

Look closely at these patients. Their dermatologist had them on a KOMEX®/KOMED® regimen.

Step 1 KOMEX®

"...toward keeping the skin meticulously clean...to decrease the usually concomitant oiliness."[1]

Cleanses thoroughly yet gently.

The detergent cleansing effect of Komex acne cleanser is uniquely enhanced with mild dissolving sodium borate particles (Scrubules) for effective yet gentle cleansing of the skin. Komex removes surface debris. Clears comedones. Cleans clogged pores. Unplugs hair follicles. And removes oils.

Mild abradancy won't damage skin.

"A frequently overlooked source of excessive friction is the practice of vigorous scrubbing in an attempt to wash acne away. The use of brushes and other scrubbing techniques can induce significant inflammatory lesions...Elimination of sources of excessive friction lead to rapid improvement[2]

The patented Komex Scrubules enable doctor and patient to control particle dissolution from 0-60 seconds, depending on water dilution. Acne patients can't overabrade with Komex. A significant exclusive.

Conditions the skin.

In fact, the skin *conditioning* effect of Komex acne soap is truly phenomenal. You can detect some of it in the patient photos. But it really must be seen—and felt.

Step 2 KOMED®

"...to peeling of the skin so that the follicular orifices are kept open."[1]

Employs a non-comedogenic form of sulfur.

Komed Lotion works beautifully with Komex.
"The sovereign remedy in the topical management of acne vulgaris is sulfur."[3]
"Sulfur...still the most effective remedy...In addition ...salicylic acid and other peeling chemicals are used in cosmetically elegant lotions..."[4]
The exclusive Komed formulation keeps skin dry and desquamating with salicylic acid and *non-comedogenic* sodium thiosulfate.

"Suspensions and creams containing elemental sulphur were shown to be capable of inducing comedones in the rabbit ear and on human backs."[5]

Has "excellent patient appeal."

"All of the patients liked the fact that (Komed) dries quickly to an invisible film...the female patients found that the lotion did not interfere with the use of non-oily cosmetics. Male patients also appreciated the lack of a masking effect, the absence of staining properties, and the fact that the lotions blend with natural skin tone."[6]

Our Town

where there's always the right topical form and strength for every clinical need ...the home of

Aristocort®

Triamcinolone Acetonide

There are alternatives...but no substitutes!

A standard for effectiveness in fluorinated topicals.

The first triamcinolone preparation to remove common sensitizers—contains no parabens, phenol preservatives, lanolin.

One of the most economical topical steroids available—in forms, strengths and sizes for every problem.

In cosmetically-pleasing forms that have become traditional patient favorites.

Indications: For relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications: Viral skin diseases, such as varicella and vaccinia hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.

Warnings: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.

Precautions: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.

Adverse Reactions: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

Supplied: *Cream 0.5%*—Per Gm.: triamcinolone acetonide 5 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.025%*—Per Gm.: triamcinolone acetonide 0.25 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; all potencies are in a water base of mono and diglycerides, squalane, polysorbate 80 USP, polysorbate 60, spermaceti USP, stearyl alcohol USP, Tenox II, and sorbitol solution USP. *Ointment 0.5%*—Per Gm.: triamcinolone acetonide 5 mg.; inactive ingredient: white petrolatum; *Ointment 0.1%*—Per Gm.: triamcinolone acetonide 1 mg.; inactive ingredient: white petrolatum. *ARISTOGEL® Gel 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., 1.8% benzyl alcohol as preservative; inactive ingredients in a water base: polysorbate 80 USP, polyoxyethylene (20) cetyl ether, glycerin USP, and citric acid USP. 775-4

Reviewers for 1976

The editors of the ARCHIVES would like to take this opportunity to thank, on behalf of themselves and the readership, the large number of dedicated individuals who have reviewed articles for the journal in 1976. As you may or may not know, every submitted paper is examined by at least two referees, as well as by the editors. Though this procedure may delay publication, it is essential for the maintenance of accuracy and quality of material published.

The following is a compilation of the names of these reviewers who have so generously given their time and expertise on behalf of the ARCHIVES. If any name is misspelled or not included, we apologize in advance. Please let us know and we will include the information as a correction in a future issue.

Chemosurgery for Melanoma

Frederic E. Mohs, MD

• **Microscopically controlled excision of melanoma by the chemosurgical method ensures complete eradication of any unsuspected outgrowths from the clinically observed tumor mass. The method differs from the chemosurgical techniques used for excision of cutaneous carcinomas in the following two respects: the tissues always are chemically fixed in situ before any incisions are made in order to minimize the chance of dissemination, and an extra margin of tissues is removed after reaching a microscopically melanoma-free plane in order to encompass possible outlying melanomatous satellites in the peritumoral lymphatics. In a series of 103 consecutive cases of melanomas of the nodular, superficial spreading, and lentigo maligna types, there were 86 determinate cases with a five-year cure rate of 50%. This is a high rate for a series in which 69% were nodular melanomas and 64% invaded to subcutaneous tissues (Clark's level 5).**

(*Arch Dermatol* 113:285-291, 1977)

In common with basal and squamous cell carcinoma of the skin, cutaneous melanoma often sends out unpredictable ramifications for some distance beyond the clinically apparent borders of the neoplasm. The eradication of these silent outgrowths is ensured by the microscopical control afforded by the chemosurgical method. However, because of the strong tendency for melanoma to invade vascular walls and hence to metastasize frequently, the chemosurgical technique differs from that used for carcinomas in two ways.[1,2]

First, in the treatment of melanoma, the tissues are always subjected to chemical fixation in situ before any incisions are made. Never is the main mass initially excised surgically prior to the layer-by-layer chemosurgical excision of the melanoma, nor is the "fresh tissue" chemosurgical technique used whereby the layers are excised without prior fixation in situ. The purpose of the in situ fixation is to minimize the chance of dislodging melanoma tissue that often dangles precariously in the lumens of the vessels. Using a sharp scalpel, the layers of fixed tissue are gently excised with care to avoid cutting into the underlying unfixed tissues.

The second way in which the chemosurgical excision of melanoma differs from that of carcinomas is that after a microscopically melanoma-free plane has been reached, an extra margin of tissues is removed. The reason for chemosurgically excising the extra margin is that melanoma, in contrast to carcinoma, fairly frequently deposits malignant cells in the peritumoral lymphatics to form satellites that may be too small to be seen at the time of the excision. Determination of the width of the extra margin is made by microscopically examining the melanoma; if it is highly anaplastic, invades vessel walls, causes extravasation, and invades deeply into the reticular dermis or beyond, the extra margin may be 3 cm or more, whereas if the microscopical features indicate a less highly malignant neoplasm, the extra margin may be 1 cm, or even less if some important facial structure is being encountered.

TECHNIQUE

To illustrate the steps of the chemosurgical technique, a case of melanoma arising in an area of melanosis on the temple is described (Fig 1).

First, dichloroacetic acid is applied to the surface until the skin whitens, indicating penetration of the keratin layer that is a barrier to zinc chloride. The zinc chloride fixative paste then is applied (Fig 1, top right). This is covered with a thin layer of

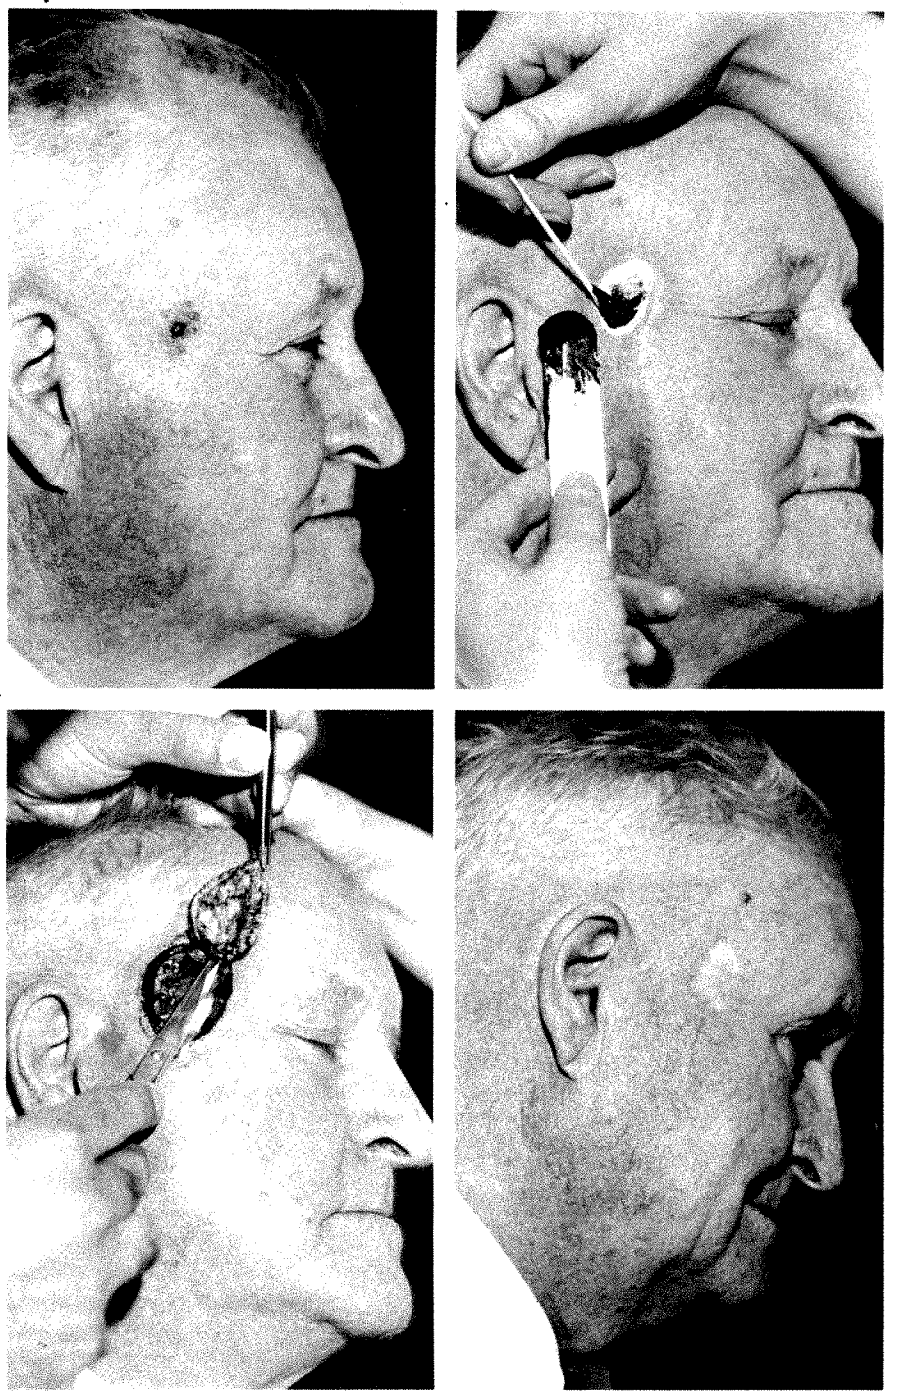

Fig 1.—Top left, Nodular melanoma of six months' duration in area of melanosis of three years' duration invasive to level 3. Top right, Application of zinc chloride paste for fixation in situ. Whitening of skin was from dichloroacetic acid that had been applied to render keratin layer permeable to zinc chloride. Bottom left, Removal of final layer of fixed tissue after eight days. Bottom right, Healed lesion after one year.

cotton that, in turn, is covered with an overlapping, petrolatum-spread, cotton dressing to provide occlusion.

After 24 hours, a layer of tissue that has been fixed in situ is excised. The incisions are made through fixed tissue with care to avoid cutting into the underlying unfixed tissue. If the melanoma is pigmented it is readily seen grossly at this stage because the black neoplastic tissue contrasts sharply with the white color of the fixed normal tissues. The fixative is reapplied and another layer is excised on the next day. If there is no grossly visible melanoma, the entire area is examined microscopically. This is accomplished by dividing the excised layer into specimens of convenient size, and having frozen sections cut through the undersurface of each of the flat pieces of tissue. The site of origin of each specimen is marked on the lesion with merbromin. Even if no melanoma is found by thorough scanning of the sections, another application of the fixative is made to provide an extra margin for the purpose of eliminating any possible melanomatous satellites in the surrounding skin lymphatics. In this case, the melanoma did not appear highly malignant because it had barely impinged on the reticular dermis (level 3 of Clark[3]), was only moderately anaplastic, and showed no evidence of invasion of vessel walls. Therefore, a 1 cm extra margin was considered adequate. After eight days, the final layer of fixed tissue had demarcated and was removed by snipping adherent strands (Fig 1, bottom left). The lesion, which was not closed or covered with a graft, healed with a smooth, whitish scar (Fig 1, bottom right).

The patient declined prophylactic dissection of the regional nodes but agreed to report for follow-up every two months. Two years later, a small nodule appeared in the lower parotid region. A superficial parotidectomy and a cervical dissection revealed four small metastatic parotid nodes but the 22 cervical nodes contained no melanoma. Although there was no recurrence of the primary tumor or evidence of metastasis in the parotid or cervical nodes, the patient died of internal malignancy five years after removal of the primary melanoma. Multiple metastatic nodules in the lungs and liver were presumed to be melanoma, but in the absence of an autopsy, the possibility of another primary malignancy was not ruled out.

THREE TYPES OF MELANOMA

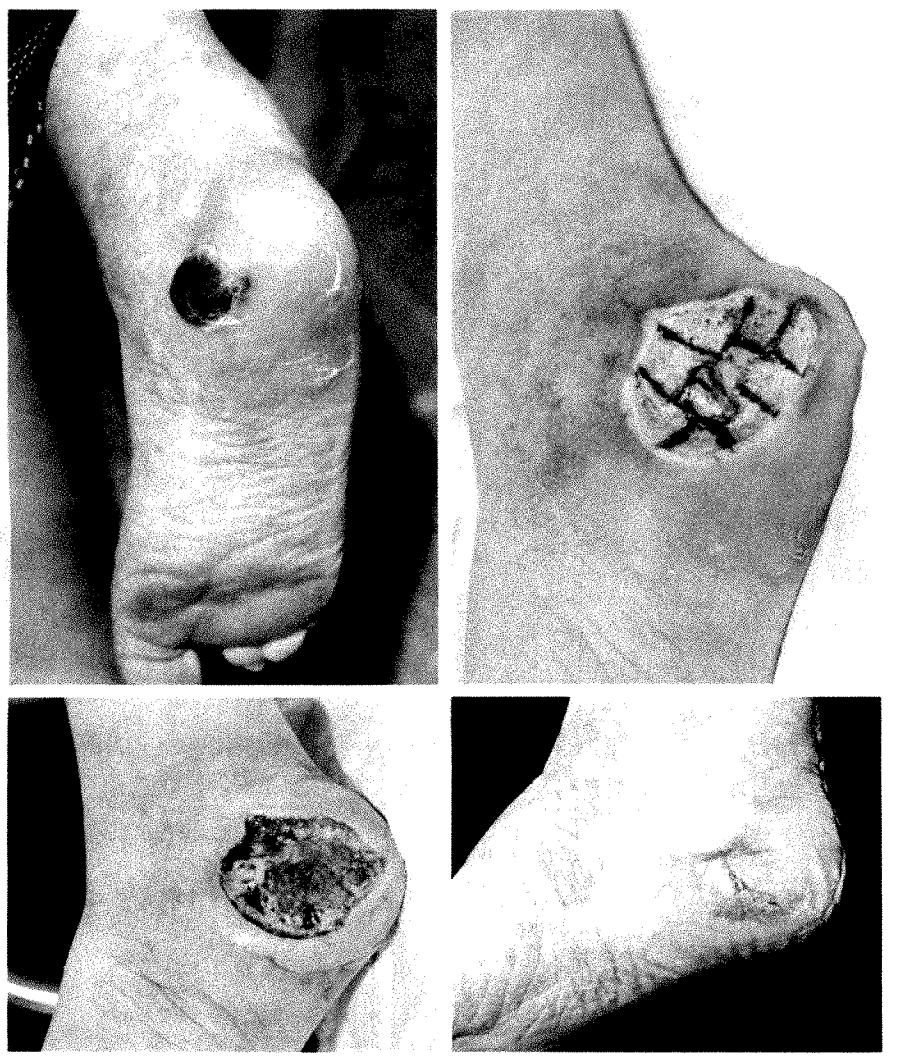
Nodular melanoma, superficial spreading melanoma, and lentigo maligna melanoma all are treated chemosurgically in essentially the same way. However, because the biologic behavior differs for the three types,[3] they are considered separately.

Nodular Melanoma

Nodular melanoma grows vertically from the onset that is in contrast to the other types of melanoma that characteristically spread peripherally in the superficial layers of the skin for a considerable time before the vertical growth phase sets in. Partly because

Fig 2.—Left, Amelanotic melanoma, invasive to level 5. Center, Granulations after chemosurgical excision that included a clinically unpredicted extension into upper eyelid. Right. Healed lesion. No recurrence after five years.

Fig 3.—Top left, Nodular melanoma of the heel, invasive to level 5. Top right, Fixed tissue when a microscopically melanoma-free level was reached. Bottom left, Granulations after separation of fixed tissue. Bottom right, Healed lesion with stabile weight-bearing scar. No recurrence of primary melanoma after five years when palpable inguinal nodes necessitated a groin dissection.



the prognosis depends on the depth of the vertical growth phase, nodular melanomas tend to have a poorer prognosis than the other types. Even when the melanoma only has spread to the extent that it impinges on the reticular dermis (level 3 of Clark), as in the case illustrated in Fig 1, there can be metastases to the regional nodes. Therefore, recognition of the danger of metastatic spread from nodular melanoma is particularly important.

One of the advantages of chemosurgery in the treatment of melanoma is that when the primary neoplasm is close to an important structure, such as the eye, the excision can be more conservative than would be safe with traditional surgical techniques. Thus, an amelanotic nodular melanoma invasive to level 5 was successfully removed from the medial canthal area despite the presence of an unexpected extension of the neoplasm into the upper eyelid (Fig 2). A very wide surgical excision might have entailed enucleation of the orbit and removal of part of the nose while a less radical surgical excision could have missed the silent outgrowth in the upper lid.

Chemosurgery has certain technical advantages in the treatment of melanomas in other areas. For example, melanoma of the sole of the foot can be reliably removed, and when the wound heals by second intention, the scar is stable and comfortable to walk on (Fig 3). The patient shown in Fig 3 declined a prophylactic groin dissection because of her age of 83. However, five years later, she permitted a therapeutic inguinal dissection

because palpable nodes had appeared. Several of the lower nodes were found to contain melanoma, but the upper ones did not. Eight months later she died of a stroke without evidence of recurrence in the primary or secondary sites.

Superficial Spreading Melanoma

Although superficial spreading melanoma often spreads peripherally for many months without danger of metastasis, it becomes increasingly more likely to metastasize when the vertical growth phase sets in. Chemosurgical excision of these lesions ensures removal of both the peripheral superficial component and the vertically-growing component (Fig 4).

Lentigo Maligna Melanoma

Lentigo maligna, or Hutchinson freckle, appears on exposed skin of elderly people and can spread slowly for many years without metastasizing, but it gains the ability to metastasize with the appearance of the vertical growth phase. Chemosurgery

Table 1.—Five-Year End Results for the Three Types of Melanoma*

Type of Melanoma	No. of Cases	Determinate Cases		
		Total	Successful	Rate of Cure, %
Nodular	70	59	26	44.0
Superficial spreading	19	16	10	62.5
Lentigo maligna	14	11	7	63.6
Total	**103**	**86**	**43**	**50.0**

*A consecutive series of microscopically proved melanomas, early to advanced, previously treated or recurrent, with or without metastasis, treated chemosurgically during a period of 31 years. Indeterminate cases are those of patients who were without evidence of melanoma when they either died or were lost from observation before completion of the 5-year follow-up.

Table 2.—Effect of Depth of Dermal Invasion on Therapeutic Results Compared With Other Series

Level (Clark)	Chemosurgery, Determinate Cases			Clark et al,[2] Determinate Cases		
	No.	Incidence, %	Cure Rate, %	No.	Incidence, %	Cure Rate, %
2	4	5	100	29	18	90
3	13	15	92	58	36	57
4	14	16	64	59	36	41
5	55	64	33	16	10	19
All	86		50	162		53

not only permits precise location and sure removal of the vertically-growing melanoma, but it also enables accurate removal of the peripheral lentigo maligna portion that often spreads farther than indicated by the grossly visible pigmentation (Fig 5). The lesions are permitted to heal by second intention; no grafts or flaps are used.

With education to impress on everyone the importance of early recognition and treatment of melanomas, the goal of removing these neoplasms while still in the safe level 2 stage is occasionally reached (Fig 6).

RESULTS

Meaningful evaluation of the five-year results of the chemosurgical treatment of melanoma requires separate classification of the data under the three types of melanoma (Table 1) and under the five levels of dermal invasion (Table 2).

As shown in Table 1, there were 103 cases of melanoma of which 86 were determinate. Of the 86 determinate cases, 43 were successfully treated giving a five-year cure rate of 50% for all three types of melanoma. As expected, the cure rate for nodular melanoma (44%) was less than that for superficial spreading melanoma (62.5%), or for lentigo maligna melanoma (63.6%). To be noted is the unusually high incidence of nodular melanoma (59/86 or 69%); this probably is because the more serious malignancies tend to be referred to a university medical center. In evaluating the statistics, the adverse effect of the high proportion of nodular melanomas has to be considered.

As shown in Table 2, the rate of cure of melanomas of all types is strongly influenced by the depth of dermal invasion. The cure rates for lesions invasive to the various levels were: 100% for level 2, 92% for level 3, 64% for level 4, and 33% for level 5. This is a pattern similar to the series of surgically treated melanomas reported by Clark et al,[3] but it will be noticed that the cure rates achieved with chemosurgery are higher for each individual level of invasion. However, the rate of cure for the combined total of lesions at all levels was 50% for the chemosurgery series as compared with 53% in Clark's series. This seeming discrepancy is readily accounted for by noting the much higher incidence of the deeper lesions in the chemosurgery series. For example, in the chemosurgery column the incidence of level 5 lesions was 64% as compared with only 10% in the surgery column. The higher cure rate in Clark's combined group reflects the earlier diagnosis of melanoma that has resulted in recent years from education of both the public and the profession regarding the importance of early recognition and treatment of growing pigmented lesions. When the present series of chemosurgically-treated melanomas was instituted in 1937, almost all of the neoplasms had invaded to level 5, but in recent years there has been definite trend toward earlier diagnosis with consequent higher rates of cure.

When the proportion of nodular melanomas and the levels of invasion, as well as the thickness, diameter, and degree of malignancy are considered, the five-year therapeutic results achieved with chemosurgery compare favorably with conventional surgery.

In the present series of 103 cases of melanoma, there were only three recurrences in the primary site (3%).

One was in an eyelid where a recurrent melanoma in an area of melanosis in the conjunctiva was being treated when the patient died of coronary occlusion. The second recurrent melanoma appeared in the center of a chemosurgical scar on the lower leg four years after chemosurgical excision of a nodular melanoma; the recurrent focus was re-excised chemosurgically, and there was no further recurrence after 15 years. The third recurrent lesion was a superficial spreading melanoma under a fingernail; the recurrence appeared proximal to the nail which had been chemosurgically excised nine months previously. Following chemosurgical re-excision, there was no further recurrence after 18 years.

COMMENT

Advantages of Chemosurgery

Advantages of chemosurgery in the treatment of cutaneous melanoma are as follows: (1) reliability, (2) flexibility, (3) conservatism, (4) low operative risk, (5) good healing, and (6) extension of operability to some patients with advanced melanoma in difficult sites where other treatment would not be feasible. Because these advantageous features form the basis of the rationale of chemosurgery in the treatment of cutaneous melanoma, they are elaborated on herewith.

1. Reliability is evidenced not only by the overall five-year cure rate of 50%, but also by the rate of recurrence in the primary site of only 3%. These statistics are the more impressive when it is considered that 69% of the neoplasms were of the most dangerous type, nodular melanoma, and that 64% of the melanomas had invaded to the subcutaneous tissues (level 5). What are the reasons for this exceptionally high degree of reliability? First, the microscopically controlled excisions ensure removal of the silent outgrowths as well as the main mass of the primary melanoma. Second, the removal of an extra margin of tissue after reaching a microscopically melanoma-free plane enhances the likelihood of encompassing any possible satellites in the peritumoral lymphatics. Third, if a clinically-undetected satellite is transected during chemosurgical excision, the neoplasm remains localized and on the surface where it can be detected early and excised chemosurgically. It is not seeded in the wound as it could be with cold knife surgery during undermining to permit primary closure or during covering of the wound with a graft or flap. Fourth, chemical fixation in situ has no tendency to increase metastasis from malignant tumors as has been shown by animal experiments[4] and by long clinical experience with the chemosurgical method.[5] This is in contrast with electrosurgical methods that produce tissue gases that may propel viable melanomatous cells through the blood vessels or lymphatics.[6] Moreover, chemosurgery avoids the danger of dislodging melanoma cells by a "milking" action such as might occur with any but the most gentle handling of the tissues during surgical excision.

2. Flexibility is achieved by the chemosurgical technique because the first excised layer safely provides adequate tissue for microscopic examination to determine how radical the subsequent excisions should be. If the frozen sections show that the lesion is not melanoma, the subsequent excisions may be appropriately conservative. Among nonmelanomatous lesions that can resemble melanoma are pigmented basal cell carcinoma, pigmented nevi of the junctional, compound, intradermal or blue varieties, histiocytoma, senile lentigo, lentigo maligna, pigmented seborrheic or solar keratoses, basosquamous cell acanthoma, hemangioma, and granuloma pyogenicum. Of course, most of these conditions are readily diagnosed clinically, and it is only rarely that their appearance resembles melanoma, but when it does, chemosurgery provides a safe means of obtaining a definite diagnosis. If the frozen sections of the first excised layer show melanoma, the assessment of the degree of malignancy permits a relatively accurate determination of the proper width of the extra margin that should be removed after reaching a microscopically melanoma-free plane. If the malignancy is observed to be moderate, a 1 cm margin may be adequate, whereas if the malignancy is high, 3 cm or more may be required. The microscopically determined degree of malignancy also aids in deciding whether or not a prophylactic dissection of regional nodes is indicated.

3. Conservatism is an advantage of chemosurgery that is particularly important in treating facial cancers where important structures, such as the eyes or facial nerve, may be endangered. Because the microscopical control ensures removal of the unpredictable ramifications, the removal of the extra margin is only for eliminating possible satellites and hence is somewhat flexible. If satellite deposits should appear at the periphery following removal of an unusually narrow extra margin, these foci have not been disturbed and still are amenable to chemosurgical excision.

4. Low operative risk results from the lack of need for a general anesthetic and the lack of complications from the breakdown of wounds or from infection. Moreover, the greater degree of conservatism, that often is safely feasible, adds to the safety of the procedure. Because most patients remain ambulatory during treatment, the danger of pulmonary complications is obviated.

5. Good healing following chemosurgical excision of melanomas often produces quite good cosmetic results even though most lesions are permitted to heal by second intention. If a defect requiring repair is produced, the well-vascularized tissues following chemosurgery provide a good base for the reconstruction that usually is delayed for at least a year.

6. Extension of operability to patients with extensive melanomas in difficult sites where surgical excision might not be feasible is an advantage. Even though the likelihood of distant metastases from extensive melanomas may dim the prospects for complete cure, the palliative value of removing the primary melanoma often is appreciable.

Management of Regional Nodes

A detailed discussion of the relative merits of prophylactic versus therapeutic dissection of regional nodes is not in the scope of this paper. To date,

there have been no well-controlled, prospective series comparing the results of prophylactic dissection with the results of very close observation of the nodes followed by therapeutic dissection as soon as the nodes become barely palpable. In the absence of such a study, each case has to be evaluated individually regarding the management of the nodes. In the early years of this series, E. R. Schmidt, MD, and I had experiences that caused us to wonder whether therapeutic dissections might not be preferable to prophylactic dissections. For example, a prophylactic groin dissection was done following chemosurgical removal of a nodular, level 5 melanoma of the lower leg. No metastatic nodes were found, but six months later, a therapeutic dissection was required because a metastasis appeared in the pubic region, medial to the usual scope of a groin dissection. Fortunately, the outcome was successful and the patient lived for 30 years without recurrence. Another patient was not so fortunate; a prophylactic neck dissection was carried out after removal of a small nodular, level 4 melanoma of the cheek; no metastatic nodes were found, but seven months later, a node appeared posterior to the scope of the usual neck dissection. A therapeutic dissection was done, but this did not prevent further cervical and finally internal metastases. The question arose: would it not have been preferable to have omitted the prophylactic dissections and to have closely observed these patients and then performed therapeutic dissections that would have encompassed the metastatic nodes beyond the edges of the usual dissection sites?

Until sufficient data are available to permit definite conclusions, it seems best to recommend prophylactic dissections if the primary melanoma has invaded the reticular dermis (level 4) or subcutaneous tissue (level 5), and if the neoplasm is located where there is a well-defined lymphatic drainage pattern. However, there often is a question as to whether a large number of patients should be subjected to unnecessary dissections to provide a somewhat questionable advantage to a relatively few individuals.

Whether or not a prophylactic dissection is done, very close observation must be insisted on. If the patient doesn't return, he should be sent a follow-up letter or called by telephone. If necessary, the help of relatives and the family physician should be enlisted to ensure close follow-up.

Because melanoma is an extremely variable disease, an optimistic attitude should be maintained as long as there is any chance of eradicating the neoplasm. Chemosurgery is an important addition to our armamentarium for the management of primary melanomatous lesions, but the propensity of melanoma to metastasize will constitute a serious problem until earlier diagnosis and treatment is achieved. The best hope of controlling the disease is education of laymen as well as physicians regarding both the early signs of melanoma and the importance of avoiding delay.

Topical Methoxsalen and Blacklight in the Treatment of Psoriasis

John W. Petrozzi, MD; Kays M. Kaidbey, MD; Albert M. Kligman, MD, PhD

• Thirty patients with recalcitrant psoriasis were treated with topical methoxsalen and blacklight (UVA). A 1% concentration either in an acetone, alcohol, propylene glycol vehicle, or hydrophilic ointment, USP, applied two hours before light exposure was highly effective. Twelve patients were completely cleared and nine were markedly improved in three to five weeks. Plaque-type and guttate psoriasis responded best while exfoliative psoriasis benefitted less. Maintenance of a phototoxic reaction in the lesion was necessary for total resolution. Topical methoxsalen and blacklight is feasible for outpatient treatment of plaque-type psoriasis of limited extent.

(*Arch Dermatol* 113:292-296, 1977)

The beneficial effects of sunlight in psoriasis have been recognized for centuries.[1] Heliotherapy remains a prominent form of treatment in many countries. By utilizing crude coal tar and ultraviolet light (UVA) from a hot quartz lamp, Goeckerman succeeded in clearing psoriasis more consistently and rapidly than was possible with sunlight alone.[2,3] Truly resistant cases to this regimen are few, and remissions may be long-lasting.[4] The action spectrum of tar resides in the long UVA region, with peak activity at about 360 nm.[5] Blacklights are a ready source of UVA. However the efficaciousness of the Goeckerman regimen is offset by the messiness and offensive qualities of coal tar. In addition, the role of UVA is still controversial in view of the comparatively large amounts of UVA emitted by the light sources generally used in this regimen.

Recently, investigators have become interested in another, cleaner photosensitizer whose mode of action is understood at the molecular level, namely methoxsalen. In the presence of the drug, irradiation with UVA inhibits the synthesis of DNA by epidermal keratinocytes.[6-8] A stable covalent bond is formed between the pyrimidine bases of nucleic acid and psoralens. In addition, interstrand cross links may be formed between psoralens and two pyrimidine bases of opposite strands of the DNA double helix. Since psoriasis is a hyperproliferative disorder, inhibition of cell multiplication by various means usually brings about regression of lesions.

As early as 1962, a preliminary verbal communication described promising results with topical methoxsalen phototherapy.[9] Strangely, further studies were delayed for ten years. Willis and Harris[10] were unable to achieve clearing of psoriatic plaques with topical methoxsalen and blacklight.[10] Walter et al[8,11] were only moderately successful. More recent studies will be described later.

Our object is to show that topical methoxsalen (8-MOP) appropriately employed with blacklight is a highly effective way of clearing psoriatic lesions.

MATERIAL AND METHODS

Patients

Twenty-nine male subjects and one female subject with longstanding psoriasis were treated. They ranged in age from 13 to 65 years. Twenty-five had chronic, stable, extensive plaque-type psoriasis; three had exfoliative psoriasis involving about 75% of the body surface. Two, including the 13-year-old female subject, had guttate psoriasis. All had been previously treated with topical corticosteroid preparations and were no longer responding adequately. Fifteen were hospitalized. The remaining 15 were outpatients.

Light Source

We used the following two UVA set ups: (*a*) For irradiation of localized plaques, a bank of five parallel 20 W fluorescent blacklights, 2 cm apart, in an aluminum reflecting housing was used (F20-T-12, Sylvania). The bank utilized five preheat

Reprint requests to Department of Dermatology, Philadelphia Veterans Administration Hospital, University and Woodland Aves, Philadelphia, PA 19104 (Dr Petrozzi).

transformers with starters. The lamp-skin distance was 13 cm to compensate for the comparatively low irradiance of the lamps. The bank used for the first 14 patients in the study utilized a less efficient ballast and emitted a lower amount of UVA energy. (*b*) For total body irradiation of extensive psoriasis, a Zimmerman cabinet was used (internal dimensions 85 cm × 70 cm). Initially (first 14 patients), this was equipped with eight UVA bulbs, two in each corner; later we increased to 28 fluorescent rapid-start blacklight tubes (General Electric F40 BL), distributed so as to encircle the patient (six bulbs on the three sides, two bulbs in each of the four corners, and two bulbs on the door). The box was lined with aluminum reflectors.

Treatment

Initially we utilized a 1% concentration of methoxsalen in hydrophilic ointment, USP. Subsequently, we evaluated a proprietary form of methoxsalen (Oxsoralen), 1% solution in an acetone, alcohol, propylene, glycol vehicle. The medications were applied liberally with cotton-tipped applicators, two hours before irradiation. The first two exposure times, three days apart, were three minutes with the bank of blacklights and five minutes in the Zimmerman box. The first 14 patients received starting exposure times of five minutes from the bank and eight minutes from the Zimmerman box since these sources emitted lower UVA energy than the modified Zimmerman box and the more efficient ballasts in the UVA bank. Because psoralen phototoxicity peaks at about 72 hours, this interval allowed time to perceive the patient's reaction and to plan dosage accordingly. Very little reaction was visible within the plaques themselves; erythema developed in the surrounding skin despite attempts to confine medication to the lesions. In fact, the phototoxic reaction in perilesional skin guided dosage increments. After the first week, patients were treated either daily (five times weekly) or three times a week. In general, the exposure could be increased by two minutes every second or third treatment after the first week. In this way, a mild to moderate phototoxic response was maintained. The dose could be more rapidly increased in blacks and patients who tanned readily while fair-skinned patients required a more gradual increase. Treatment could usually be completed with a maximum exposure of about 25 minutes with the UVA bank and 35 minutes in the cabinet. We did not realize until afterwards that the ultraviolet meter used to measure irradiance gave excessively high readings; hence we record the dose in minutes rather than joules.

Therapeutic Response of Patients*

Patient No.	Age, yr	Sites Treated	Light Source	Therapeutic Response	No. of Treatments

*Patients 1 through 14 received exposures from lower UVA energy sources.
†Treated three times a week on alternate days.

In patients with very thick plaques, two nightly occlusive applications of 15% salicylic acid in a propylene glycol:ethanol solution (85%:15%) were used before phototherapy to remove scales. Unfortunately, the number of plaques receiving these applications were not tabulated and compared with those not receiving salicylic acid applications. This data therefore could not be clearly presented.

Clearing of the lesions was graded as follows: 1+, diminished scaling; 2+, decreased erythema and infiltration; 3+, minimal infiltration; and 4+, complete clearing. The treatment period ranged from three to five weeks.

Control plaques were treated in each patient with the vehicle and UVA irradiation. The use of UVA alone and the vehicles alone were abandoned after it was shown to be completely ineffective in the first six patients.

RESULTS

Therapeutic Response

Twelve of 30 patients cleared completely after 12 to 28 treatments (Table). Eleven of these had plaque-type and one had guttate psoriasis. Nine others were markedly improved, and nine showed a partial response (2+ to 1+) (Fig 1 through 4). Three of the latter patients had generalized exfoliative psoriasis. It was our clinical impression that lesions over the trunk generally responded more promptly than those over the extremities, though the number of patients was too small to be definitive. Since patients treated three times per week received five to nine less treatments over the study period, we cannot compare the results of the two treatment regimens. It is possible that while taking longer, treating three times per week may be equally or more effective. Patients who did not achieve a greater than +2 response by five weeks were deemed to be resistant. We found that several more weeks of intensive treatment failed to bring about clearing. Control plaques

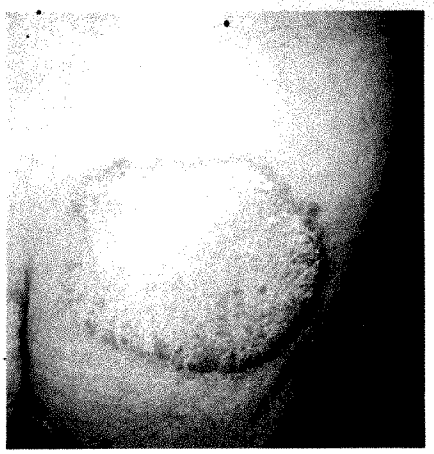

Fig 1.—Patient 5 before treatment.

Fig 2.—Patient 5 after 21 treatments with 1% methoxsalen in hydrophilic ointment.

Fig 3.—Patient 13 before treatment.

Fig 4.—Patient 13 after 28 treatments with 1% methoxsalen solution.

never cleared and generally did not change, even slightly. Therefore, they have been excluded from the tabulation of the grades of response. Responses to the higher energy UVA sources did not appreciably increase the effectiveness of the treatment. It did, however, decrease the duration of treatments in patients who tanned quickly and required longer exposures. We did not tabulate the number of psoriatic plaques that received and did not receive salicylic acid, but it is our clinical impression that thick plaques respond better when pretreated with salicylic acid.

Adverse Reactions

Pruritus.—This occurred in eight patients usually after three to four treatments and was associated with marked perilesional erythema. Pruritus usually persisted throughout treatment though it could be somewhat diminished by giving antihistamines. One patient (No. 1) discontinued therapy after five treatments because of stubborn severe pruritus.

Hyperpigmentation.—This was conspicuous in all white patients. The cleared sites were intensely pigmented, providing an impressive record of the distributions of lesions. In most cases, the hyperpigmentation that also involved a small area of surrounding skin disappeared in about two months. In three cases, the pigmentation was evident for four months and in two others, it lasted for six months.

Koebner Reaction.—Two patients who showed severe phototoxic reactions after six to ten exposures developed a Koebner reaction in the perilesional skin at the site of the phototoxic reaction after four to seven days. Nonetheless these new lesions also responded while treatment was continued with lower doses.

Blistering.—Three patients treated with the bank developed small blisters at the margins of psoriatic plaques, one after the first exposure, another after the third, and the last one after the 13th exposure. Treatment of these plaques was discontinued for a week and then reinstituted at lower doses with no difficulty. All three later achieved complete clearing.

Follow-Up Observation

Seventeen patients could be followed for one year without further treatment.

Eight who were completely cleared stayed in remission for two to ten months. Six of these were clear for an average of 2½ months, one for 6 months, and one for 10 months.

All nine incompletely cleared patients relapsed to pretreatment levels in three to five weeks.

Special Studies

Interval.—In a previous study,[12] it was determined that UVA exposures two hours after the ingestion of methoxsalen was the optimum time interval for production of a phototoxic reaction. We carried out a similar study with 1% methoxsalen cream on the normal skin of the back in four patients 30 minutes, 1, 2, 4, 6, and 24 hours after open application. Irradiation was with the UVA bank, 5 cm from the skin for two minutes. The reactions were examined 72 hours after exposure.

Results.—At one half and one hour, reaction varied from 1+ to 3+. Peak reactions (+4) developed at two hours in all four patients. The response had begun to diminish after three hours (+2, +3), clearly so after four and six hours (+1 to +2). No reaction occurred after 24 hours in any patient. (Grading: +1 erythema, +2 erythema with edema, +3 marked erythema and edema, +4 vesiculation, 72 hours after exposure).

Concentration.—In the same four

patients, occluded and unoccluded applications (0.2 mg from a tuberculin syringe) of 0.1% and 1% methoxsalen in hydrophilic ointment were compared after irradiation at 5 cm for two minutes with the UVA bank two hours after application. The agents were rubbed in vigorously with a cotton-swab, and when occluded, a plastic wrap was taped over the site. Readings were made 72 hours after exposures.

Results.—With occlusion, 0.1% methoxsalen was only slightly less phototoxic than 1% as judged by the same grading system as above. Three patients differed by one grade, that is, +2 vs +3 and +3 vs +4. One patient went from +1 to +3 with the 1% methoxsalen. Without occlusion, 0.1% methoxsalen produced no reaction in one patient, +1 reaction in two patients, and +2 reaction in one patient. This compared to +2 reaction in two and +3 reaction in two patients using 1% methoxsalen.

Comparison of Solution with Cream on Psoriatic Lesions.—In symmetrical plaques of five patients, 1% methoxsalen in the liquid vehicle was compared to hydrophilic ointment. Each plaque was treated five times weekly for three weeks and irradiated with the UV-A bank two hours after open application.

Results.—The solution was equal to the hydrophilic ointment in only one patient who cleared completely at the same rate with both preparations. In the other four, the hydrophilic ointment caused clearing in two, with marked improvement in the other two. The solution gave moderate improvement in two and only slight improvement in the remaining two. The rate of clearing was slower with the solution. This was particularly evident in thick plaques.

COMMENT

The combination of 1% methoxsalen followed in two hours by individually adjusted doses of UVA sufficient to produce a phototoxic reaction was highly efficacious in recalcitrant plaque-type psoriasis. We selected the concentration and the interval between application and irradiation after having evaluated these variables on normal persons. Our results with topical phototherapy are more impressive than those of previous workers. Willis and Harris[10] found no benefit with 0.1% methoxsalen irradiated after 30 to 45 minutes for 15 minutes with three sunlamps and three blacklight bulbs placed 17.5 to 22 cm from the skin. In our view, they failed because the concentration of methoxsalen was too low, the interval was too short, and the dosage of UVA was too small (too few lamps at too great a distance).

Walter and Voorhees[11] were more successful. Two of eight patients cleared, and eight of 11 improved. They used trioxsalen in an ethanol: propylene glycol solution, in concentrations up to 0.25%, irradiating two hours later with four blacklight bulbs for as long as 20 minutes, three times weekly. Topically, trioxsalen is as phototoxic as methoxsalen.[13] Again, a higher concentration would probably have improved their results.

Weber[14] used 0.15% methoxsalen in isopropyl alcohol followed in one hour by 8 to 12 minute exposures to 30 high-intensity blacklight bulbs in a cylindrical chamber. He achieved total clearing in 34 and great improvement in 24 of 74 patients. The higher quantity of irradiation from 30 UVA bulbs apparently offset the low concentration. Weber's patients received treatment for five days a week for two weeks with a week interval before re-exposures for another two weeks.

The beneficial results obtained by Tronnier and Schule[15] in seven psoriatics are surprising to say the least. They irradiated every three to four days with a bank of five blue-black UVA bulbs at 50 cm for 8 to 20 minutes, ten minutes after application of 0.15% methoxsalen. We could not clear psoriatic plaques in two patients treated in a similar manner (unpublished data).

Recently, Parrish et al[16] have utilized oral methoxsalen (up to 50 mg) followed in two hours by exposures in a chamber housing 48 newly developed, high energy UVA fluorescent bulbs. Their results were dramatic; 21 of 21 psoriatics achieved complete resolution. They used the term "photochemotherapy" for this treatment; their claims are being amply confirmed by ourselves and many others. Treatment was given on alternate days. Remission occurred after 12 to 20 exposures. For widespread psoriasis, oral administration of methoxsalen is certainly the method of choice. It eliminates the burden of applying medication to every plaque and is not attended by unsightly hyperpigmentation at cleared sites. On the other hand, topical methoxsalen might be advantageous when there are only a few lesions. Moreover, in special locations such as the palms and soles, topical therapy might be more practical. Topical methoxsalen may be a useful adjunct to oral phototherapy for treating very thick lesions or stubborn plaques in special locations. We are currently evaluating this "touch-up" approach. We would emphasize that extensive psoriasis requires oral phototherapy.

We have lately treated a good many more psoriatic patients with topical phototherapy. Our current views may be summarized as follows:

1. Thick keratotic plaques should be descaled prior to the start of treatment. Salicylic acid under occlusion for two to three nights is the best drug for this purpose. We used 15% salicylic acid in a propylene glycol:ethanol base, but a proprietary preparation of 6% salicylic acid in propylene glycol can be employed. It is our clinical impression that without prior sal acid treatment to thick plaques, the response to therapy is less effective. Non-keratotic plaques do not require sal acid treatment.

2. The optimal interval between application and irradiation is two hours.

3. We prefer 1% methoxsalen in hydrophilic ointment. Patients must be cautious against sloppy applications. The agent must be restricted to the psoriatic lesions to minimize the risk of blistering. The exposures must be long enough to create a visible phototoxic reaction in the surrounding skin. The times will increase as therapy proceeds but must be adjusted to each individual according to skin type. Useful information can be obtained by inquiring about ease of sunburning and difficulty in tanning. With a bank of five blacklights (Syl-

vania BL F20T12) 13 cm away, the maximum exposure in most instances will rarely exceed 25 minutes and is usually 15 to 20 minutes. However, some patients may build up a tremendous tolerance and withstand 30 to 40 minutes.

4. Daily irradiation brings about more rapid clearing than on alternate days, most likely in our experience because it resulted in a greater number of treatments given in the study period. It is possible that alternate day treatment may be effective. Caution is advised in the first week until the patients' responses are known. The first dose is given on Monday and the second on Thursday since phototoxicity to methoxsalen reaches a peak in 48 to 72 hours. We now start with three minutes from our UVA bank in fair-skinned subjects who sunburn easily and tan poorly. Exposures can be more rapidly advanced in those who tan rapidly. In thick palmar plantar psoriasis, exposures may begin at 15 minutes and have to be increased to 45 minutes daily. It should not be casually assumed that all blacklights are equivalent either in intensity or spectral quality. We can vouchsafe only for the lamps we used (Sylvania BL F20T12 and General Electric F40 BL).

Finally, there is the question of photocarcinogenicity. Tumors on the ears of albino mice were produced in 53% of the animals treated with topical 0.1% methoxsalen in ethanol and irradiated with UVA five days a week for 127 days.[17] Using the same animal model, similar tumors were produced in 100% of mice treated with 3% crude coal tar and UVA irradiation. Recently, the carcinogenic effect of topical methoxsalen was demonstrated in hairless mice irradiated with the xenon arc solar simulator two hours a day, five days a week for 40 weeks.[18]

It is anybody's speculation whether oral or topical methoxsalen phototherapy will produce cancers in humans with the exposures required to keep psoriasis in remission. It is a fact that despite the known carcinogenicity of coal tar, instances of tumor induction in humans treated over decades by the Goeckerman regimen are exceedingly rare and of these, none are indisputable. The same can be said for centuries of use of plant psoralens in countries where solar insulation is very high. We think the risks are slight in relation to the torments of the disease.

Recently, a novel approach to the photochemotherapy of psoralen has been offered by Fischer and Juhlin.[19] They utilized a 15 minute bath with trioxsalen (0.5 mg/liter) and irradiated immediately after the bath with 8 dysprosium gas discharge lamps. This light source emits a low dose of UVB as well as high intensity UVA. Seventeen of 18 psoriatic patients were cleared within six weeks.

Margaret McQuiggan rendered technical assistance in the treatment of these patients.

Shortage of Full-Time Faculty in Dermatology

Clayton E. Wheeler, Jr, MD; Robert A. Briggaman, MD; Ivor Caro, ME, BCh, FF Derm

• A persistent shortage of full-time faculty exists in dermatology. Despite the addition of 124 new full-time faculty since 1971 through 1972, 136 training programs in 1974 through 1975 were actively seeking 88 new full-time faculty and believed they needed 243. With a net gain of 30 new faculty a year, it will take 2.93 years to add 88 new faculty that are being actively sought and 5.16 years to add 155 more that are urgently needed. During this eight years, demand for new faculty will increase, so that figures of need may remain essentially unchanged in 1982 through 1983 as between 1971 through 1972 and 1974 through 1975. Expertise that was most needed was in immunology, electron microscopy, histopathology, microbiology, and biochemistry; many accept faculty in any area or with no special training. Measures should be taken to attract and retain more dermatologists in full-time academic positions.

***(Arch Dermatol* 113:297-301, 1977)**

In our report in 1973,[1] we called attention to the existence of a severe shortage of full-time faculty in 1971 through 1972. Since then we have conducted two surveys, one in 1972 through 1973 and one in 1974 through 1975, to determine whether the number of full-time faculty in dermatology has increased and whether a shortage still exists. In this communication, we compare the results of the 1971 through 1972 survey with the results of the 1972 through 1973 and 1974 through 1975 surveys. Although there has been an increase of 124 persons in the total number of full-time faculty since 1971 through 1972, the demand for new faculty has increased, so that the degree of shortage remains about the same as it was in 1971 through 1972.

MATERIALS AND METHODS

In our 1971 through 1972 survey, a five-page questionnaire was sent to all active or potential training units in dermatology in the United States and Puerto Rico, which was a total of 133 training units. A less extensive, two-page questionnaire was sent to the same units in 1972 through 1973, except that category D, which consisted of three unclassified units, was omitted. In 1974 through 1975, the two-page questionnaire was sent to all of the actual or potential training units in dermatology, which at that time numbered 136. Questions in the shorter, two-page questionnaire were taken from the original five-page questionnaire; hence, the questions that were pertinent to this study were the same for the three periods of survey and should produce comparable data for these periods. All training units either returned completed questionnaires or were called by telephone. We therefore obtained information from all of the units.

For purposes of our surveys and this report, the training units were divided into three categories. Category A included training programs in medical schools in which there were approved dermatology residencies; category B included training programs in medical schools in which there were no approved dermatology residencies; and category C included approved dermatology residency programs outside medical schools. In the 1971 through 1972 and 1972 through 1973 periods, there were 67 units in category A, 44 units in category B, and 19 units in category C. In 1972 through 1973, five programs in category B were well along in developing residency programs, and in 1974 through 1975, these were shifted to category A, since their programs were then approved. Since new medical schools were activated, new schools were added to category B in the 1974 through 1975 survey. There were also some rearrangements in category C; one of these programs was transferred to category A, one was phased out, and two new ones were added. In 1974 through 1975, there were 74 units in category A, 43 units in category B, and 19 units in category C.

A full-time faculty member was defined as one who spends about half of his time in teaching, research, or administration, regardless of the source of his income. He might spend the other half of his time in various combinations of teaching, research, patient care, or administration. He might derive his income from school salary, from a practice within the geographic confines of the school, from a private office outside

Accepted for publication June 29, 1976.

Reprint requests to North Carolina Memorial Hospital, Chapel Hill, NC 27514 (Dr Wheeler).

of the school, or from combinations of these. The major requirement was that he spend half of the total working hours in teaching, research, or administration. We recognize that this definition includes fully salaried faculty, geographic full-time faculty deriving income from practice within the confines of the institution, and functionally geographic full-time faculty deriving all or most of their income from practice outside of the confines of the institution. This definition differs from that used by most schools and by the American Medical Association, but we can see no real difference in "faculty function" between a fully salaried member who spends half of his time seeing private patients in the institution to generate funds for his own salary and departmental activities, a geographic full-time member who does about the same, and a "part-time" faculty member who generates all of his personal income from practice outside of the institution, yet works half-time at teaching, research, or administration at the institution.

RESULTS

Number of Full-Time Faculty in Dermatology in 1971 Through 1972, 1972 Through 1973, and 1974 Through 1975

The number of full-time faculty in the three survey periods is presented in Table 1, which shows the number of dermatologic units, the total number of faculty, and the number of faculty per unit in each of our three categories. During the four-year period, the average number of full-time faculty in category A increased from approximately four to approximately five per training unit. The number increased from approximately three to approximately four in category C. The number remained essentially unchanged in category B. Overall, the average number of full-time faculty increased from 2.5 to 3.25 per training unit.

According to our survey, the total full-time faculty increased from 320 in 1971 through 1972 to 444 in 1974 through 1975, an increase of 124 positions, or 38.7%. By another definition of full-time faculty, the AMA lists filled budgeted full-time positions in dermatology as follows: 192 positions in 1971 through 1972,[2] 232 in 1972 through 1973;[3] 246 in 1973 through 1974,[4] 262 in 1974 through 1975.[5] This is an increase from 1971 through 1972 to 1974 through 1975 of 70 positions, or 36.5%. By either method, it appears that there has been an increase of 36% to 38% in full-time faculty in dermatology during the four-year period.

Distribution of Full-Time Faculty Among the Training Units

Table 2 shows the distribution of full-time faculty among the training units in the three categories for the 130 programs in 1971 through 1972 and the 136 programs in 1974 through 1975.

Although the average number of faculty per training unit in category A increased from about four in 1971 through 1972 to about five in 1974 through 1975 (Table 1), Table 2 shows that there were two faculty per unit most often in 1971 through 1972, and there were three faculty per unit most often in 1974 through 1975. Obviously, figures for the average faculty per unit were skewed by the few programs with large members of faculty; there were five programs with over ten faculty in 1971 through 1972 and six with over 12 in 1974 through 1975. Despite an increase in average faculty per unit from 2.74 to 3.68 in category C, the most frequently reported number of faculty per unit in the two survey periods was three. Perhaps the most noteworthy item in Table 2 was the large number of training units without full-time faculty, ie, 37 in 1971 through 1972 and 30 in 1974 through 1975. As anticipated, these were chiefly in category B, which includes schools without residency training programs.

Number of New Full-Time Faculty Being Actively Sought in 1974 Through 1975

The number of new full-time faculty members being actively sought in 1974 through 1975 in comparison with

1971 through 1972 and 1972 through 1973 is presented in Table 3. According to respondents to the questionnaires (chiefs of programs in dermatology, chairman of medicine departments, and deans), funds to pay these faculty members were either at hand or there were excellent possibilities of obtaining the money if suitable faculty could be found. In all three survey periods, essentially all of the respondents indicated that it would be difficult to find these faculty members. According to our data, 88 new faculty members were being actively sought by 61 training units in 1974 through 1975 in comparison with 99 and 95 faculty members in 61 training units in 1972 through 1973 and 1971 through 1972, respectively. Although 61 training programs were actively seeking faculty in each of the three survey periods, the same programs were not seeking new faculty each year; it is only coincidence that the number of programs seeking faculty was 61 in each period. The number of faculty being actively sought in the three categories of training units was similar in the three survey periods, despite the total gain of 124 full-time faculty in the period from 1971 through 1972 to 1974 through 1975, as shown in Table 1.

It is likely that some units were not actively seeking faculty, but hired new faculty when exceptional persons appeared. For instance, in 1971 through 1972, the five larger programs stated that they were not actively seeking new faculty. Yet by 1974 through 1975 each of these five programs had added at least two new members, which is one more member per program than the overall average increase. Therefore, there is reason to believe that there is more real seeking for new faculty than has been expressed by the programs.

Number of New Full-Time Faculty Believed Needed in 1974 Through 1975

Those in charge of developing the dermatologic units were asked to state the number of new full-time faculty that they would be seeking if they had adequate funds (Table 4). They were urged not to inflate the number and to list only those who were really needed. The 136 units indicated that they needed 243 new faculty in 1974 through 1975. This compared with the need expressed by the 130 units for 221 in 1972 through 1973 and 264 in 1971 through 1972.

Type of Training Being Sought in New Full-Time Faculty

The types of training being sought in new faculty members by those in charge of developing dermatologic units, whether new or well established, are listed as follows:

Discipline	Times Requested
Immunology	169
Electron microscopy	99
Patient care	80
Histopathology	76
Microbiology	61
Anything faculty desires	55
Research, undifferentiated	38
Biochemistry	34
Teaching	27
Pediatric dermatology	11
Pharmacology	10
Surgery	10
Geriatric dermatology	9
Genetics	9
Oncology	8
Virology	5
Photobiology	5
Physiology	4
Molecular biology	4
Radiation	3
Mycology	3
Biophysics	3
Rehabilitation	2
Administration	2
Tissue culture	2
Cell biology	2
Contact dermatitis	2
Community dermatology	1
Syphilology	1
Industrial dermatology	1
Metabolism	1
Radioautography	1
Allergy	1
Pigmentation	1
Train paramedics	1
Endocrinology	1
Cytogenesis	1
Teenage dermatology	1
Train technicians	1
Teach in family practice	1
Histochemistry	1

Some of these areas could be combined, but we list them to indicate the diversity of the disciplines being sought in new faculty members. Obviously, training programs usually listed a number of areas that might be acceptable for a given new faculty person, since the number of acceptable disciplines far exceeds the number of new faculty being actively sought. This table is a composite of disciplines sought as shown by the three surveys.

COMMENT

The degree of shortage of full-time faculty in dermatology appears to be as great in 1974 through 1975 as it was in 1971 through 1972, despite the addition of 124 new faculty members in the four-year span. Obviously the demand for faculty has exceeded the supply to produce the chronic shortage. This increasing demand for new full-time faculty is related to several factors. New medical schools are being activated with a corresponding need to provide new dermatology faculty. Existing medical schools with no full-time faculty are beginning to appreciate the need for full-time faculty. A major factor is that existing dermatology teaching units, both in and outside of medical schools, are expanding to meet the greatly increased demands placed on them. These demands include the following: more teaching of medical students due to the greatly increased number of students (freshman enrollment has increased from 12,361 to 14,963, and total enrollment has increased from 43,650 to 54,074 from 1971 through 1972 to 1974 through 1975) and changing techniques of teaching these students; more teaching of nondermatologic residents, especially family medicine, medicine, and pediatrics, which is due to their increased numbers and their increasing appreciation of the need for dermatologic knowledge; more teaching of dermatology residents; more teaching of nondermatologist- and dermatologist-practicing physicians (partly as a result of continuing education requirements); greater involvement in patient care; more complicated research; more administrative duties in schools and hospitals; more involvement of dermatology in organized medicine at a national level. New activities are being added, such as

training of allied health professionals, assistance in self-evaluation programs, and continuing education for practicing physicians. All indications are that the demand for new full-time faculty will increase, probably at a rapid rate.

One shortage area stands out above all others, namely, the complete absence of full-time faculty in 30 medical schools (29 without dermatology residency training programs and one with a dermatology residency training program). Three of these schools are two-year basic science schools, and two are in early phases of development, where a full-time dermatologist might not be essential; but the remainder are operational, and many have been in operation a long time. Although there may be notable exceptions in these schools, teaching of dermatology to medical students and primary care residents (pediatrics, medicine, family medicine, obstetrics, etc,) and continuing dermatologic education of primary care physicians is for the most part inadequately done; dermatological research is usually nonexistent; and there is little participation of dermatologists in the administrative affairs of the school or of the associated hospitals. Since dermatologic disease constitutes a significant portion, possibly 10% to 15% of the practice of primary care physicians, and since there is increasing emphasis on the training and continuing education of primary care physicians, it seems essential that dermatology be adequately taught in all medical schools. Some of the schools that place the greatest emphasis on training primary care physicians appear to be the weakest in terms of dermatology faculty and curriculum, which is paradoxical. It continues to be a real challenge to the specialty of dermatology to ensure that dermatology is adequately taught in all medical schools, but especially in those without full-time faculty, which we previously defined.

What is the possibility of relieving the shortage of full-time faculty in dermatology if our current rate of addition of 30 new faculty members per year to the total pool continues? At this rate it will take 2.93 years to acquire the 88 faculty that is currently being actively sought, and another 5.16 years to acquire the additional 155 that is considered needed. Unless the rate of training and recruiting new faculty is increased or the rate of loss is decreased, or both, there will remain a shortage of faculty for eight years or until 1982 through 1983, assuming that there is no further growth and expansion of faculty beyond the need perceived for 1974 through 1975. However, as discussed previously, the demand for new faculty will in all likelihood increase over the next eight years, so that we suspect that figures of need for faculty in 1983 will look like they do for 1974 through 1975. Even if the faculty being actively sought and the additional faculty considered needed can be recruited, the size of dermatologic faculties will still be small, ie, an average of five faculty members per unit, a figure that appears to be well below the critical mass to accomplish what these units should be doing. At least, in these days of concern about training too many specialists, dermatologic faculty appears to be one group in which there appears to be little danger of creating a surplus in the forseeable future.

For reasons presented in this communication, measures should be taken to increase the number of full-time faculty in dermatology. Further study should be done to determine if the shortage is due to too few academic dermatologists being trained or too many leaving academic dermatology after being trained, or a combination of these two. Efforts should be made to accept persons into training who have firm commitments to academic dermatology. Measures should be taken to make academic dermatology more attractive and more competitive with full-time practice and practice with part-time teaching.

One of the reasons for preparing this report in 1973 and again at this time was to inform prospective full-time academicians that many job opportunities exist. A registry or job clearinghouse has been established through the joint efforts of the American Academy of Dermatology (AAD) and the Association of Professors of Dermatology with the purpose of getting the job hunter and the job opportunity together. This joint effort has supported a booth at the annual AAD meeting for the past two years and has conducted questionnaire surveys to identify residents who are interested in academic positions. Potential academicians might contact the AAD office or Mark A. Everett,

MD, at the University of Oklahoma School of Medicine, who represents the Association of Professors of Dermatology in this effort. In addition to contacting this registry, we suggest that any would-be academician send a letter of inquiry and a curriculum vita to those units in which he might have an interest. The names and addresses of dermatologic training units may be obtained from the *1975-76 AAMC Directory of American Medical Education*,[6] the AMA *Directory of Approved Internships and Residencies 1974-75*,[7] and the secretary of the Association of Professors of Dermatology.

Another reason to prepare this report was to point out that program directors are looking for some area of expertise in new faculty members that they are trying to recruit. The would-be academician would do well to identify and pursue a special area early in his training so as to enhance his job opportunities later. The particular area of expertise is less important than that the prospective faculty member has such an area. However, having acquired no special area of expertise should not deter a dedicated, prospective full-time faculty member from searching for a position. At the present time immunology, electron microscopy, histopathology, microbiology, and biochemistry are the most popular special areas (Table 5). It is encouraging to note that patient care, any special area that the prospective faculty member desires, undifferentiated research, including clinical investigation and teaching, occupy equally high positions on the list.

The final reason to prepare this report in 1973 and again in 1976 was to point out that the shortage of full-time faculty constitutes an urgent problem that should be of primary concern to all dermatologists. As we wrote in 1973, the fountainhead of our specialty consists of the training of new dermatologists and of the acquisition of new knowledge of the skin and its diseases. These activities take place primarily, though not exclusively, in our schools and hospitals. Full-time faculty, as defined by us in previously, is required for dermatology to hold and enhance its position in schools and hospitals. It is in schools and hospitals that decisions are made concerning the position of dermatology in the curriculum; the amount of money, space, and equipment for teaching, research, and administration; and the amount of dermatology clinic and bed space for teaching purposes. It is also in schools and hospitals that practical decisions are made concerning which disease is to be cared for by what type of physician, ie, what the purview is of a given specialty. If the position of dermatology is lost in schools and hospitals, few dermatologists will be trained, and little research will be done. If the position of dermatology is lost in schools and hospitals, the specialty will lose its identity, and pressures will eventually arise to eliminate or restrict the specialty. If the position in schools and hospitals is lost, the specialty will wither and die, no matter how many patients are being seen in the offices of the dermatologists who have already been trained. The shortage of full-time faculty and maintenance of full-time faculty should therefore be a concern of all dermatologists, whether they are academically inclined or exclusively interested in private practice.

Gastrointestinal Absorption of Griseofulvin From Corn Oil-in-Water Emulsions

Effect of Amount of Corn Oil Ingested in Man

Theodore R. Bates, PhD; Henry J. Pieniaszek, Jr; Joel A. L. Sequeira; James E. Rasmussen, MD

• The effect of the amount of emulsified corn oil ingested on the gastrointestinal absorption of griseofulvin in man was assessed after oral administration of 5, 10, 15, or 30 gm doses of a corn oil (40% w/w)-in-water emulsion dosage form, each containing 250 mg of microsize griseofulvin. For comparison, griseofulvin absorption from two-125 mg commercial tablets of ultramicrosize drug dispersed in polyethylene glycol 6,000 was also determined. Griseofulvin was almost completely absorbed from the microsize drug emulsions and ultramicrosize drug tablets, whereas 50% of an oral dose is absorbed from commercial microsize griseofulvin tablets. Only 4 gm of emulsified corn oil (as a 10-gm dose of emulsion) is required to maximize the uniformity and extent of griseofulvin absorption. The emulsion dosage form is uniquely suited for pediatric use.

(*Arch Dermatol* 113:302-306, 1977)

Griseofulvin, a systemic antifungal antibiotic with limited aqueous solubility (15 mg/liter at 37 C), is slowly and incompletely absorbed in man after oral administration of microsize drug as an aqueous suspension[1,2] or as commercial tablet dosage forms.[2-4] The average amount absorbed from these dosage forms is approximately 50% of the dose. These poor absorption characteristics are thought to account for the lack of clinical response of some patients treated with conventional dosage forms of microsize griseofulvin.[5-7]

Crounse[6] demonstrated that in man, oral administration of microsize griseofulvin (1 gm dose) with a high fat meal (bacon, eggs, cream, and butter)[5] results in increased gastrointestinal absorption of this antibiotic as reflected by increased four and eight hour serum concentrations. The lack of information on the actual lipid content of the meal (assumed to be considerably more than 60 gm) precludes proper utilization of this finding by clinicians since the degree of potentiation of griseofulvin absorption is a function of the amount of coingested dietary fat.[5,6] This approach to enhancing the absorption of microsize griseofulvin is also limited by patient compliance and the necessity of maintaining patients on high lipid diets for extended periods of time.

Previous studies in this laboratory[2] indicated that oral administration of microsize griseofulvin (500 mg dose) dispersed in a corn oil-in-water emulsion dosage form vehicle can result in a twofold enhancement in the amount of griseofulvin absorbed in man as compared to administration of the antibiotic in an aqueous suspension vehicle or in commercial tablet dosage forms. Twelve grams of corn oil, in an emulsified form, was used to produce this maximal increase in griseofulvin absorption. It would be highly desirable if the amount of emulsified corn oil coingested with griseofulvin could be further reduced.

The present bioavailability study was designed to assess the effect of the amount of emulsified corn oil ingested with a 250 mg oral dose of microsize griseofulvin on drug absorption and to compare the oral absorption of the microsize griseofulvin corn oil-in-water emulsion with that of commercial ultramicrosize griseofulvin tablets (Gris-PEG). The latter formulation, which contains ultramicrosize griseofulvin dispersed in polyethylene glycol (PEG) 6,000, has also been reported to be twice as available as commercial tablets of microsize griseofulvin.[8,9]

mg, were purchased on the open market.

Corn oil-in-water emulsions, containing 250 mg of dispersed microsize griseofulvin per 5, 10, 15, and 30 gm of emulsion, were prepared as described previously.[10] These amounts of corn oil-in-water emulsion correspond to 2, 4, 6, and 12 gm of emulsified corn oil, respectively.

Prior to use, all dosage forms were assayed in triplicate for drug content by the spectrophotometric method described earlier.[10]

Absorption Studies

A four-way crossover study (latin square design) was performed on four healthy, nonobese, male volunteers between the ages of 23 and 25 years and weighing between 70 and 87 kg. Informed consent was obtained after the nature of the procedures had been fully explained. The criteria for subject selection included a routine physical examination, urinalysis,

UNIVERSITY OF MEDICINE LIBRARY

and blood chemistries. The subjects were instructed not to consume any drugs or alcoholic beverages for seven days prior to, and for four days following griseofulvin administration.

In each phase of the crossover study, a single 250 mg oral dose of griseofulvin was administered at 8 AM to each subject after an overnight fast (at least eight hours) as two-125 mg ultramicrosize griseofulvin tablets with 100 ml of water (treatment A), as 30 gm of corn oil-in-water emulsion with 70 ml of water (treatment B), as 15 gm of corn oil-in-water emulsion with 85 ml of water (treatment C), and as 10 gm of corn oil-in-water emulsion with 90 ml of water (treatment D). The treatments were administered according to the schedule shown in Table 1 and were separated by a one-week "wash-out" period. At the end of the fourth treatment week, the same four subjects ingested a 250 mg dose of microsize griseofulvin as 5 gm of corn oil-in-water emulsion with 95 ml of water.

Urine was collected from each subject immediately prior to drug administration (time zero) and at 2, 4, 6, 8, 12, 48, 72, and 96 hours after drug administration. The pH and volume of each specimen was recorded, and an aliquot was stored in the frozen state until assayed in duplicate for 6-desmethylgriseofulvin content. No food was permitted until four hours after drug administration.

Free 6-desmethylgriseofulvin in the urine was determined by a double extraction, differential spectrophotometric method.[11] Total 6-desmethylgriseofulvin (free and the glucuronide conjugate) was assayed by the same procedure after incubating an aliquot of the urine specimens with 500 units of β-glucuronidase (bacterial-type II, Sigma Chemical Co, St. Louis) for two hours at pH 6.8 and 37 C.[2]

RESULTS

It is well established that the rate and extent of absorption (bioavailability) of griseofulvin in man can be determined from urinary excretion data for the major metabolite 6-desmethylgriseofulvin and its glucuronide conjugate.[1,2,4,9,12,13]

No statistical difference (analysis of variance) in urine pH was found to exist among the five study conditions at any collection period examined (Table 2). Thus, differences noted in the amounts of total 6-desmethylgriseofulvin excreted in the urine accurately reflect differences in the bioavailability of griseofulvin.

The cumulative amounts of total 6-desmethylgriseofulvin excreted in the urine as a function of time after oral administration of the ultramicrosize griseofulvin tablets and 10, 15, and 30 gm of corn oil in-water emulsions are listed in Table 3. Excretion of total 6-desmethylgriseofulvin was completed within 72 hours after administration of griseofulvin under each of the four study conditions, indicating that 96 hours was more than adequate to assess the bioavailability of griseofulvin.

Total 6-desmethylgriseofulvin excretion rate profiles, which reflect the time course of griseofulvin concentrations in the plasma,[1,4] were quite similar after administration of the ultramicrosize griseofulvin tablets and 10, 20, and 30 gm of the corn oil-in-water emulsion formulations (Figure). No substantial differences existed among the four formulations

Table 5.—Bioavailability of Griseofulvin After Oral Administration of a 250 mg Dose of the Antibiotic in Tablet and Emulsion Dosage Forms

	Cumulative Amount of Total 6-Desmethylgriseofulvin Excreted in 96 Hours (Percent of Dose)			
Subject	Ultramicrosize Griseofulvin, 2 Tablets	Corn Oil-in-Water Emulsion, 30 gm	Corn Oil-in-Water Emulsion, 15 gm	Corn Oil-in-Water Emulsion, 10 gm
1	82.48	81.68	82.12	75.28

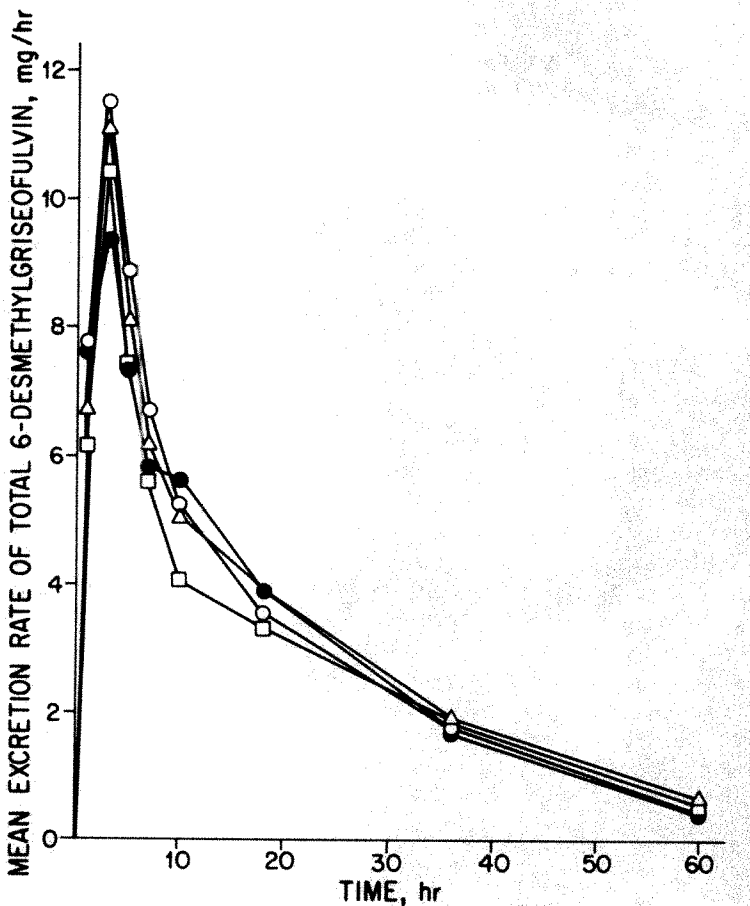
with respect to the mean maximum excretion rate of total 6-desmethylgriseofulvin (Table 4), suggesting that comparable maximum body levels of griseofulvin were attained after their administration. The maximum excretion rate of total 6-desmethylgriseofulvin consistently occurred three hours after administration of either 10, 20, or 30 gm of corn oil-in-water emulsion whereas, the time of occurrence of the maximum excretion rate varied from one to seven hours after administration of the ultramicrosize griseofulvin tablets (Table 4).

The cumulative amounts of total 6-desmethylgriseofulvin ultimately excreted in the urine for each subject after each formulation, expressed as percent of the oral dose of griseofulvin, are listed in Table 5. Statistical analysis of these data indicated no significant differences among the ultramicrosize griseofulvin tablets, and the 10, 20, and 30 gm corn oil-in-water emulsion formulations. Free and conjugated 6-desmethylgriseofulvin together account for approximately 84% (mean of five subjects) of all of the urinary metabolites of griseofulvin in man.[1] A comparison of this average maximum value with the average 96-hour excretion values reported in Table 5 suggests that almost all of the 250 mg oral dose was absorbed from the commercial ultramicrosize griseofulvin tablets and the microsize griseofulvin corn oil-in-water emulsions. The bioavailability of griseofulvin from these formulations is approximately *twice* that found from microsize griseofulvin tablets currently in clinical use.[2-7] In addition, the administration of corn oil caused no statistically significant change in the fraction of total 6-desmethylgriseofulvin ultimately excreted in the urine as free 6-desmethylgriseofulvin (Table 6). The mean fractions calculated for the corn oil-in-water emulsion formulations and the ultramicrosize griseofulvin tablet (Table 6) were comparable to literature values.[1-4]

COMMENT

The improved absorption of griseofulvin after administration of the ultramicrosize griseofulvin tablets or



Excretion rate of total 6-desmethylgriseofulvin as a function of time after a 250 mg oral dose of griseofulvin as ultramicrosize griseofulvin tablets (closed circles), as a corn oil-in-water emulsion, 30 gm (open circles), as a corn oil-in-water emulsion, 15 gm (triangles), and as a corn oil-in-water emulsion, 10 gm (squares). Each point represents mean of four fasting subjects.

Table 7.—Maximum Excretion Rate and Cumulative Urinary Excretion of Total 6-Desmethylgriseofulvin (6-DMG) After Oral Administration of a 250-mg Dose of Griseofulvin as 5 gm of Corn Oil-in-Water Emulsion

the corn oil-in-water emulsions is produced by different mechanisms. In the case of the tablet formulation, the increased absorption is thought to be due to the presence of ultramicrosize griseofulvin particles (as a dispersion in the water soluble carrier, polyethylene glycol 6,000) which, because of their greater surface area, dissolve at rates appreciably more rapid than those of the microsize griseofulvin particles contained in conventional tablets.[1,8,9] The particle size fraction of griseofulvin (microsize) in the corn oil emulsion formulation is the same as that used in commercial tablets. Hence, the enhanced absorption of griseofulvin from the corn oil-in-water emulsion is probably due to the ability of emulsified lipid (corn oil) to inhibit gastrointestinal motility and to stimulate gallbladder evacuation.[2] Bates and Sequeira[2] have proposed that the inhibitory effect of emulsified corn oil on gastric emptying results in a slow transfer of undissolved griseofulvin into the small intestine. The smaller amounts of drug present in the proximal intestine at any particular time after oral administration of the corn oil emulsion, coupled with the inhibitory effect of lipid and/or the fatty acids liberated during its digestion on intestinal motility, allows the drug more time to dissolve in the region of the small intestine where absorption is believed to be optimal. The presence of emulsified corn oil and/or its digestion products (oleic and linoleic acids) in the intestine also stimulates the evacuation of bile from the gallbladder, which increases the dissolution rate of this poorly soluble antibiotic.[2]

Dose-response relationships have been demonstrated for the effects of ingested lipid or long chain fatty acid on gastrointestinal motility[14,15] and gallbladder evacuation[16] in man. A similar relationship may exist between the amount of corn oil ingested and the bioavailability of griseofulvin at emulsion doses of less than 10 gm. In fact, as noted in Table 5, all subjects absorbed slightly less of the 250 mg dose of antibiotic when it was administered with 4 gm of emulsified corn oil as 10 gm of corn oil-in-water emulsion than when either 6 gm (15 gm of corn oil-in-water emulsion) or 12 gm (30 gm of corn oil-in-water emulsion) of emulsified lipid was ingested with the antibiotic.

This observation prompted an additional absorption study in which the same four subjects received a 250 mg dose of microsize griseofulvin as 5 gm of corn oil-in-water emulsion, an amount equivalent to 2 gm of emulsified corn oil. The results of this experiment are summarized in Table 7. Paired *t*-tests reveal that no significant differences in either the maximum excretion rate of total 6-desmethylgriseofulvin or in its time of occurrence exist between the 5 gm dose of corn oil-in-water emulsion and either the 10, 15, or 30 gm dose of corn oil-in-water emulsion (Tables 4 and 7). However, the bioavailability of microsize griseofulvin was significantly lower after administration of 5 gm of corn oil-in-water emulsion than after administration of either 15 gm ($P < .01$) or 30 gm ($P < .02$) of corn oil-in-water emulsion (Tables 5 and 7). Even though the absorption of griseofulvin from 5 gm of corn oil-in-water emulsion was not optimal, the absorption-enhancing effect of emulsified corn oil was still evident. The bioavailability of griseofulvin was reduced, on the average, by less than 20% when ingested with only 2 gm of emulsified corn oil (Tables 5 and 7).

The results of this investigation indicate that the bioavailability of griseofulvin can be maximally enhanced upon its administration to man with as little as 4 gm of emulsified, unsaturated lipid in the form of a corn oil-in-water emulsion formulation. Also, unlike the solid dosage forms (tablets and capsules) of griseofulvin currently in clinical use, the emulsion dosage form affords the greatest uniformity in drug absorption, is uniquely suited for pediatric use, and allows for facile dosage adjustments.

This investigation was supported in part by a grant-in-aid from Westwood Pharmaceuticals, Inc, Buffalo, NY.

Superficial Mycoses

Treatment With a New, Broad-Spectrum Antifungal Agent: 1% Clotrimazole Solution

Nardo Zaias, MD, Francisco Battistini, MD

• A 1% clotrimazole solution was used as an antifungal for Tinea versicolor, Cutaneous Candidiasis and Dermatophytosis. All studies were double-blind and controlled, active vs vehicle. The final evaluation was made at a two-week follow-up after the treatment was stopped, which for most of the clinical conditions studied, was 28 days. The 1% clotrimazole solution was found to be effective with no local irritation noted.

(*Arch Dermatol* 113:307-308, 1977)

In 1958,[1] Gentles introduced griseofulvin as an antifungal agent that produced systemic effects. Many investigators followed Gentles obvious hint, and after 18 years of human use experience, griseofulvin is still the best and safest antidermatophytic agent producing systemic effects. The unique antifungal specificity demonstrated by griseofulvin against dermatophytic fungi in 1958, a breakthrough for the time, is now in 1976, its Achilles' heel. From 1962 to 1963, thiabendazole, a substituted benzimidazole, enjoyed the unique characteristic of being both safe and a superb antidermatophytic agent applied topically; it was, however, never used as such until 1974.[2] The era of the substituted imidazole led to the realization that one drug could be effective against various types of fungi and yeasts. The intent of this study is to present data on clotrimazole, a new, broad-spectrum antimycotic agent.[3]

TINEA VERSICOLOR

Protocol

Patients were enrolled in this study if their direct microscopic examinations revealed the typical spores and hyphae of Pityrosporum furfur. Either strip-tape, or microscopic slide method was used. The patients were treated twice daily for only 14 days. At end of treatment, they were again examined clinically and microscopically for traces of the fungus. The last follow-up examination was done 14 days after medication was stopped.

Results

The Table presents the data from a double-blind study on the efficacy after 14 days treatment and after 14 days follow-up posttreatment. Clotrimazole was 86% effective vs 52% vehicle effectiveness.

CUTANEOUS CANDIDIASIS

Cutaneous candidiasis is an opportunistic infection on the surface of the skin. Its source, the gastrointestinal tract, supplies the protagonist in quantities that are dispersed over the body surface. In the intertrigenous area of the skin, the yeast thrives, yet

Patients Clinically and Mycologically Cured at End of 14-Day Posttreatment Follow-up*

	1% Clotrimazole Lotion	Polyethylene Glycol 400 Vehicle
Tinea versicolor (68 patients)	30/35, 86%	17/33, 52%
Cutaneous candidiasis due to *C albicans* (99 patients)	49/56, 88%	14/43, 33%
Tinea cruris or corporis (73 patients)	33/34, 97%	6/39, 15%
Tinea pedis (33 patients)	12/16, 75%	7/17, 35%

*Double-blind studies.

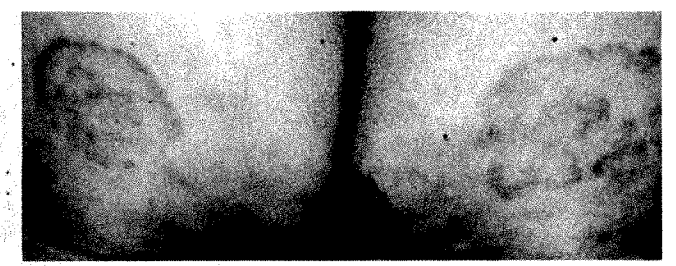

Fig 5.—Tinea corporis by Trichophyton rubrum.

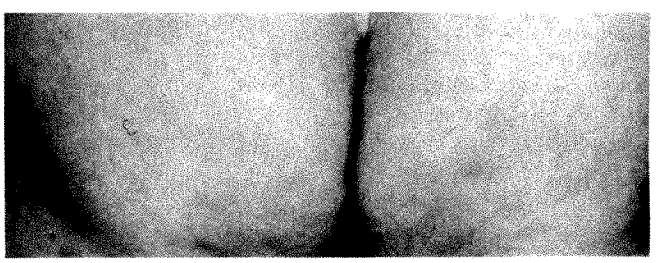

Fig 6.—Patient after two-week posttreatment follow-up. Treatment four weeks.

normally is kept under control by the antimicrobial environment, as well as host factors. When the delicate balance is upset, the organism thrives and replicates in great numbers, and the clinical lesions result.

Protocol

Patients with clinical candidiasis were enrolled in this study. Pretreatment cultures and direct microscopic confirmation of candidiasis (Gram smear or KOH preparation) were performed. Only patients with germ tube producers *(Candida albicans)* were entered into this study. The patients were treated for 28 days and again examined and cultured. After 14 days following the cessation of treatment, the patients were again examined clinically and mycologically.

Results

The Table shows the results of the double-blind study of 1% clotrimazole vs placebo vehicle. Clotrimazole lotion has effectively cured (Fig 1 through 4), clinically and mycologically, 88% of patients treated as compared to 33% cured in the placebo group.

TINEA CORPORIS—TINEA CRURIS DERMATOPHYTOSIS

Protocol

Patients suspected of having tinea corporis or tinea cruris, clinically, were entered in the study after demonstration of a hyphal element by direct microscopy. To remain in the study, cultures had to be positive for a dermatophyte. Patients were treated for 28 days at the end of treatment period, and were examined again clinically and mycologically (Fig 5 and 6). Final clinical and mycological examination was done at 14 days posttreatment.

Results

The Table shows clotrimazole to be 97% effective vs 15% cure in vehicle group.

TINEA PEDIS

Protocol

Patients suspected of having tinea pedis were studied. A pretreatment clinical, mycological culture and direct microscopic examination were performed prior to inclusion into the study. Patients were treated for 28 days and again clinically and mycologically studied. The final clinical and mycologic study was done 14 days after cessation of treatment.

Results

The Table shows the 75% of patients using 1% clotrimazole were determined as cured clinically and mycologically 14 days after treatment was stopped, as compared to 35% cured by vehicle.

This investigation was done in cooperation with "the treatment of superficial mycoses cooperative study group": Humberto Bogaert, MD, Antonio Coiscu, MD, and Rosa Rojas, MD, Santo Domingo, Dominican Republic; Fabio Londono, MD, Bogota, Colombia; Guillermo Ortiz, MD, San Juan, Puerto Rico; and Alvaro Vivas, MD, and Jorge Zavala, MD, Merida, Yucatan, Mexico.

Serum IgE in Dermatitis and Dermatosis

An Analysis of 497 Cases

Sean O'Loughlin, MD; Jose L. Diaz-Perez, MD; Gerald J. Gleich, MD; R. K. Winkelmann, MD, PhD

• Serum IgE values from 497 patients with various forms of dermatitis, dermatosis, and tinea pedis were analyzed statistically and compared with values from 95 normal controls. The median and geometric mean values were significantly elevated (except in acne without atopy, lichen planus, and tinea pedis), even after exclusion of patients with a history of atopy or of cutaneous reaction to food or drugs. Serum IgE levels and atopic dermatitis have a close correlation. A modest positive correlation ($p \cong .05$) appeared between the log serum IgE level and peripheral blood absolute eosinophil count in 80 cases of atopic dermatitis. A unique group of adult nonatopic patients had acquired generalized dermatitis and markedly elevated serum IgE levels (> 12,000 ng/ml). Our results suggest that, in most common dermatologic disorders, elevated serum IgE is a secondary phenomenon rather than a primary causative factor.

(*Arch Dermatol* 113:309-315, 1977)

The discovery of IgE[1-4] and the development of radioimmunoassay techniques for IgE estimation[5-7] were major stimuli to the investigation of allergic diseases. Although serum IgE concentrations are low in normal health, they are high in atopic dermatitis,[8-14] asthma and allergic rhinitis,[7,15-18] and parasitic disorders.[19-21] Serum IgE levels in dermatologic conditions other than atopic dermatitis usually have been reported as normal,[8,10,12,13,22,23] but many of these reports were based on very few cases.

We have analyzed serum IgE levels in 497 Mayo Clinic patients who had various forms of dermatitis, common dermatoses, or tinea pedis. The results indicate that serum IgE is frequently elevated in dermatologic diseases.

Accepted for publication July 29, 1976.

Reprint requests to Section of Publications, Mayo Clinic, 200 First St SW, Rochester, MN 55901 (Dr O'Loughlin).

MATERIAL AND METHODS

Subjects

The controls were 95 normal nonatopic subjects. The 497 dermatology patients were divided into three clinical groups: dermatitis, dermatosis—both with nosologic subdivisions—and tinea pedis (Tables 1 and 2).

All diagnoses were made by experienced dermatologists at the Mayo Clinic.

Dermatitis

Atopic Dermatitis.—These patients had classic pruritic, acute and chronic, lichenified dermatitis that involved particularly the flexural areas. Most of the patients had had infantile eczema or gave a family history of atopic disease. Many had other markers of atopy such as previous or current allergic respiratory disease.

Neurodermatitis.—This localized or generalized, pruritic, lichenified dermatitis reaction occurred, usually in mid or late life, without current or previous atopy. The patients responded negatively to intradermal allergic and methacholine (Mecholyl) skin tests. Patch testing, performed in 31 cases, gave negative results. Ten patients were distinctive clinically in that they had marked prurigo nodularis lesions— intensely pruritic, hard, globular nodules of a chronic nature, often symmetrically distributed and widely spaced, and occurring particularly on the limbs.

Contact Dermatitis.—In these patients, a delayed hypersensitivity reaction caused dermatitis after exposure to contact allergens or compounds to which they had become sensitized. The diagnosis was confirmed by patch tests. All patients were tested with a standard test tray as recommended by the International Contact Dermatitis Committee. In addition, 40 patients had patch tests using a vehicle tray, and 12 patients had further specific antigen tests. A positive patch test produced erythema and papules that were usually mildly pruritic, developed often within 24 hours after application, and were present consistently at 48 hours. Significant positive reactions to patch-test agents occurred in all patients (and individual patients often showed a positive reaction to more than one allergen): 1.0% aqueous potassium chromate, 11 patients; 1.0% ethylenediamine, 10; 1:1,500 phenylmercuric acetate, 9; 1.0% aqueous nickel nitrate, 9; 1.0% sodium lauryl sulfate, 6; 1.0% paraphenylenediamine, 6; 2.5% aqueous formalin, 6; various detergents, 5; rubber mix, 5; 1.0% aqueous glutaraldehyde, 4; hydrocarbon series, 4; parabens, 3; medications, 3; 0.1% aqueous mercury chloride, 3; 1.0% alcohol benzocaine, 3; 25% potassium iodide in petroleum, 3; 30% turpentine in oil, 3; hair shampoo, 2; polyethylene glycol, 2; 5% aqueous copper sulfate, 2; 1:1,000 thimerosol, 2; 10% propylene glycol, 1; 5% Bismark brown, 1; 0.5% aqueous sodium arsenate, 1; and cinnamon, 1.

Nonspecific Dermatitis.—This subgroup included the following disorders (Table 1) in which no evidence of contact, atopic, or fungal factors could be established.

1. Nummular dermatitis was manifested by chronic, recurrent, pruritic, coin-shaped plaques of closely set papulovesicles on an erythematous base. They occurred particularly on the trunk and limbs.

2. Eczematoid dermatitis was defined as a nonspecific, poorly demarcated, erythematous area of exudation and crusting of variable degree, which occurred without preferential localization.

3. Exfoliative dermatitis was defined as a universal, chronic inflammation with widespread exfoliation. The cause in these cases was unknown.

4. Stasis dermatitis was defined as eczema of dependent limbs associated with venous insufficiency but uncomplicated by contact dermatitis from local therapy or infection.

5. Infectious eczematoid dermatitis was defined as superficial inflammation caused by staphylococci, streptococci, or both. It sometimes originated from foci of infection in an ulcer or sinus tract.

6. Asteatotic dermatitis was manifested by dry, scaling, cracked, and fissured skin involving the limbs particularly. It was seen more commonly in the elderly and was most prominent during the winter months.

Dyshidrotic Dermatitis.—This was an acute, recurrent, or chronic vesicular eruption on the palms, soles, or digits. Fungal and contact allergenic features were absent.

Dermatoses

In view of their classic clinical presentation, the following common dermatoses do not require individual definition: psoriasis, urticaria, acne vulgaris, alopecia areata, pityriasis rubra pilaris, and lichen planus (Table 2).

Tinea Pedis

This was defined as a severe, chronic and recurring, symptomatic dermatophytic infection of the foot, proved by KOH examination and culture. The patients were not atopic and had no other dermatologic disease. Culture revealed that 11 patients had *Trychophyton rubrum;* 3, *Trychophyton mentagrophytes;* and 1, *Epidermophyton floccosum.*

Measurement of IgE

Serum IgE protein was measured by double antibody radioimmunoassay. Previous studies with this method in our normal subjects revealed a range from 1 to 2,700 ng/ml and a median of 80 ng/ml. The 94% confidence interval of serum IgE values was 6 to 780 ng/ml.[7] Although the control sera were not examined concurrently with the test sera, we recently have tested sera from 30 healthy blood donors

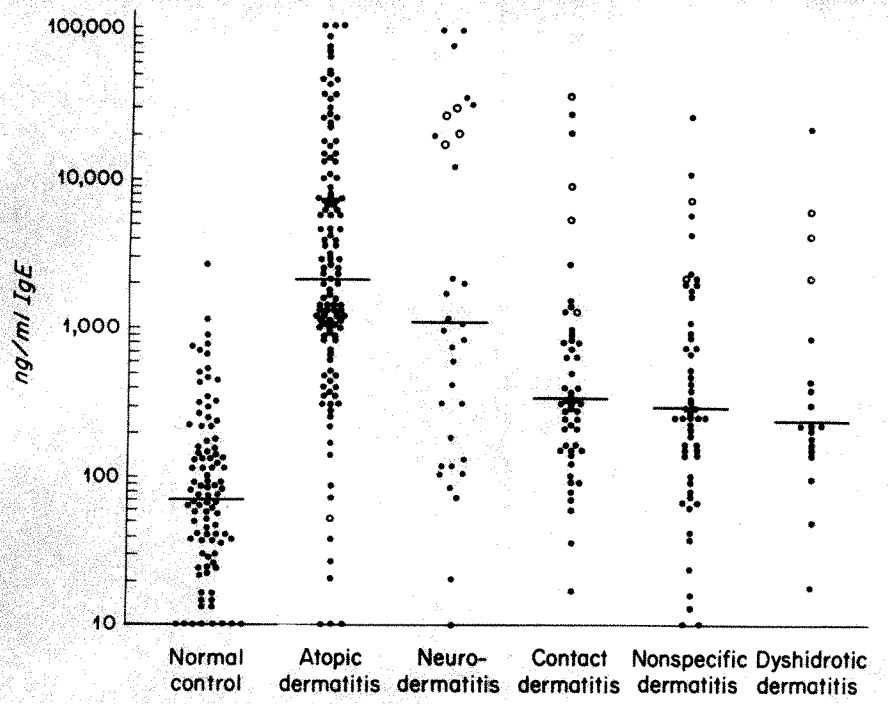

Fig 1.—IgE in dermatitis. In neurodermatitis, contact dermatitis, and nonspecific dermatitis, open circles represent patients with a history of cutaneous reaction to food or drugs. In other groups, open circles represent a history of atopy. A crossbar indicates the geometric mean of each group after excluding both types of patients.

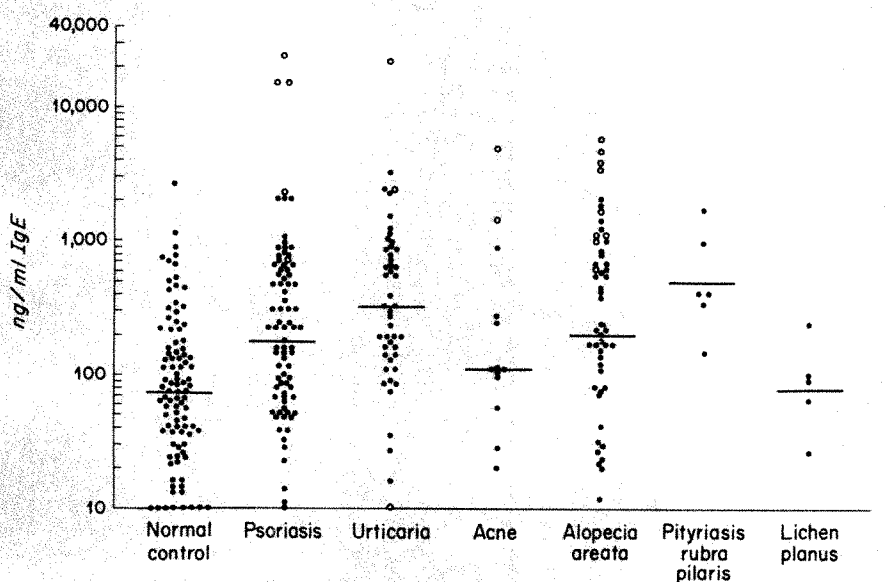

Fig 2.—IgE in common dermatoses. Open circles represent patients with a history of atopy. A crossbar indicates geometric mean of each group after exclusion of these patients.

and obtained an arithmetic mean of 114 ng/ml, a median of 58 ng/ml, and a 95% confidence interval of 12 to 699 ng/ml. These results are remarkably similar to those reported in 1971[7]: arithmetic mean 179 ng/ml, median 80 ng/ml, and 94% confidence interval 6 to 780 ng/ml. These results encourage belief that the assay has not changed since its introduction and that the use of the original controls is appropriate here. In this study, serum IgE levels are expressed in nanograms per milliliter. Data from the literature reported as International Units (IU) are converted to weight (1 IU = 2.35 ng)[24,25] for comparison purposes.

Stool examination for ova and parasites was performed in 80% of the cases with moderate or markedly elevated serum IgE concentrations.

Statistical Analysis

The median, the geometric mean, and the 95% confidence interval for the geometric mean (CI) of serum IgE levels were estimated for each subgroup. To correct for the skewed distribution of serum IgE values in each subgroup, we used a log transformation of serum IgE values. Employing Student's *t*-test (two-tailed), we compared each subgroup and the tinea pedis group with the normal control group investigated previously by Gleich et al.[7] In addition, where appropriate, we excluded all patients who had a history of atopic diathesis and again compared each subgroup with the control group. (Atopic patients were those who previously or currently had atopic dermatitis, allergic rhinitis, or allergic asthma.) Also, in certain dermatitis subgroups—neurodermatitis, contact dermatitis, and nonspecific dermatitis—the cases with histories suggesting cutaneous manifestations of immediate hypersensitivity reaction to foods or drugs were excluded from a second analysis of the subgroups (Table 1 and 2). Although suggestive of atopy, this type of reaction was not considered sufficient to classify any of these subgroups as atopic dermatitis.

The relationship between serum IgE concentrations and peripheral eosinophil count was assessed in 80 cases of atopic dermatitis.

GENERAL FINDINGS

The serum IgE concentration of each member of each group or subgroup and each control subject is plotted in Fig 1 through 3.

Table 1 and 2 present clinical, laboratory, and statistical data from the control group, from each dermatitis and dermatosis subgroup, and from the tinea pedis group.

Figure 4 shows the percentage of patients in each subgroup with serum IgE levels exceeding the upper limit of normal IgE (780 ng/ml).

The median and geometric mean levels for serum IgE are significantly elevated in all categories except nonatopic acne, lichen planus, and tinea pedis. This elevation remained after patients with a history of atopy or of cutaneous reaction to food or drugs were excluded. The P value ($< .05$) in the acne group is not conclusive but significant.

The results of stool examination for ova and parasites were negative in all patients tested. As reported previously, the prevalence of intestinal para-

sites is low among allergic patients at this institution.[26]

COMMENT

Dermatitis

Atopic.—Serum IgE concentrations greater than 10,000 ng/ml were present in 30% of these cases. One patient with severe active allergic asthma had a concentration of 55 ng/ml (signified by unfilled circle in Fig 1). Figure 5 shows a modest positive correlation ($p \cong .05$) between the log serum IgE level and peripheral blood absolute eosinophil count in 80 cases of atopic dermatitis (correlation coefficient = 0.22).

The geometric mean level of 2,865 ng/ml from our series may be compared to 2,733, 1,159, 2,768, and 2,270 reported from other large series.[8-11] Our median level of 2,346 ng/ml is slightly less than 2,639 ng/ml found earlier in 58 patients at this institution.[14] Our results also are comparable to those reported in the German literature.[12,13]

Concentrations greater than 1,000 ng/ml were measured in 76% of our cases and in 82% of cases reported by Juhlin et al.[8] A history of either allergic asthma of hay fever, or both, was recorded in 37% of their cases. Serum IgE levels within the normal limit were obtained in 24% of our cases, contrasting with the 62.5% in a series of "pure" atopic dermatitis cases from which patients with concurrent allergic diseases and those receiving hyposensitization or systemic corticosteroid therapy were excluded.[11] Stone et al[14] have confirmed a relationship between extent of atopic dermatitis and serum IgE levels.

The absence of excessive IgE in some patients with atopic dermatitis might be explained by the finding of non-IgE, reaginic antibodies in some experimental animals.[27] The IgE reaginic antibody in allergic asthma[28] and "short-term, anaphylactoid, IgG antibodies" in food allergy[29] exist in humans, and naturally occurring anti-IgE antibodies[30] or other undetected antibodies may exist as well.

Neurodermatitis.—Of the 32 cases, 11 had serum IgE levels exceeding 10,000 ng/ml. Among these 11, the median was 35,736 (Table 3). The highest levels were seen in three patients with chronic acral dermatitis who have been described previously by Winkelmann and Gleich.[31] They were unique in that the acral involvement was the predominant feature, and may constitute a distinct group. We have included the three cases in the neurodermatitis group because the manifestations and characteristics of the two conditions are similar in many respects. At the present time we are inclined to regard these patients as a subset of those with neurodermatitis. Supporting this view is Cormane's[32] independent recognition of a form of acral dermatitis having a high percentage of circulating lymphocytes bearing IgE.

The other patients with levels exceeding 10,000 ng/ml all had severe generalized dermatitis but without acral predominance, and none had spontaneous or induced evidence of atopy (Table 3). This latter group points to the existence of a separate nonatopic form of dermatitis that has high levels of serum IgE and a chronic course. We believe this is a significant clinical observation emphasizing that stimuli other than the usual atopic stimuli can be related to IgE levels.

The relationship of serum IgE levels to prurigo lesions is uncertain. There was a significant elevation of the median level of serum IgE. The presence of prurigo was not specifically related to serum IgE levels, however, since six of the ten patients had serum IgE values less than 500 ng/ml. Analysis of the ten cases failed to show a relationship between serum IgE levels and extent of lesions, duration of lesions, age of patient, or peripheral eosinophil count.

There has been scant reference in the literature to serum IgE levels in neurodermatitis or prurigo. Two cases of prurigo simplex has serum values of 774 and 2,081 ng/ml[13]; one case of prurigo nodularis had a serum value of 445 ng/ml.[8] In a case of generalized prurigo nodularis, the concentration was 5,404 ng/ml.[10] The range of our cases was 26 to 5,814 ng/ml.

Contact Dermatitis.—Published reports give geometric mean levels of 202 ng/ml and 909 ng/ml in contact dermatitis.[8,10] Ours was 336 ng/ml. Elsewhere, normal levels were found in 6 cases[12]; a mean of 540 ng/ml was found in ten cases that was compared with a mean of 163 ng/ml in 100 normal subjects.[13]

Our data suggest that elevated

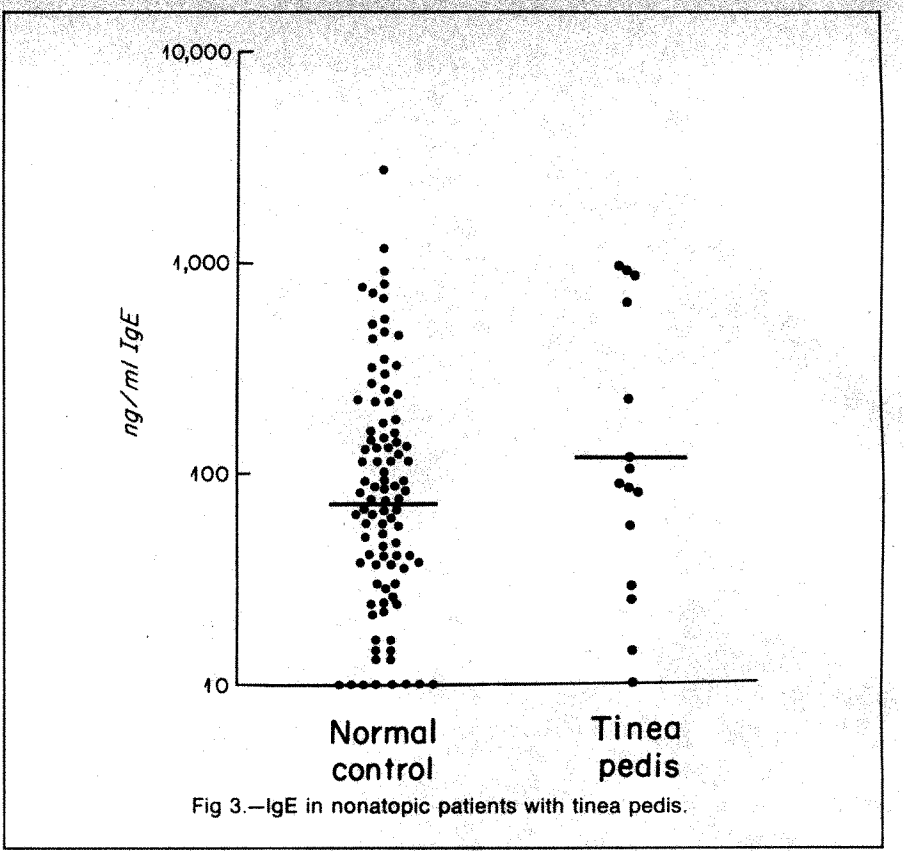

Fig 3.—IgE in nonatopic patients with tinea pedis.

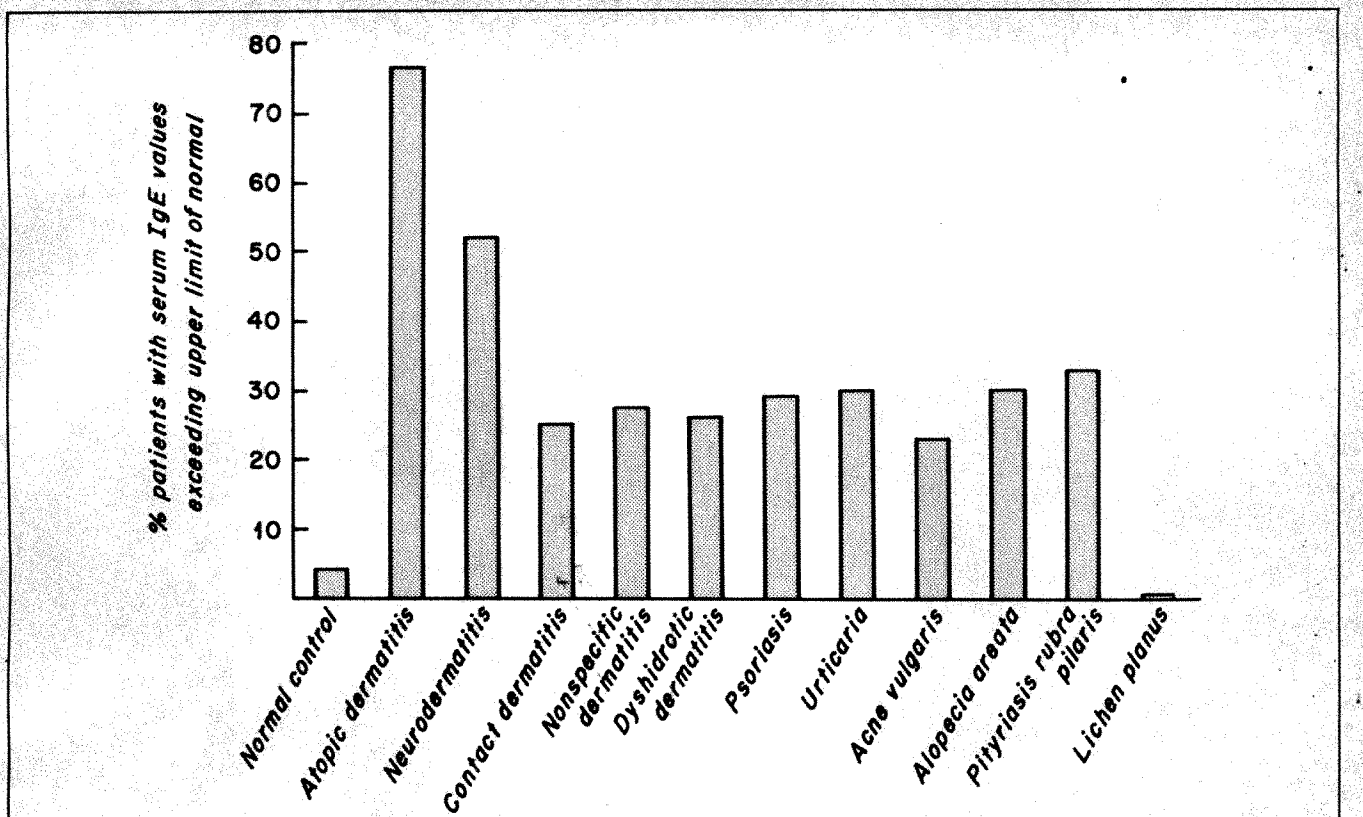

Fig 4.—Percentage of patients with serum IgE values that exceeded upper limit of normal.

serum IgE levels may occur in patients who have severe contact dermatitis and that serum IgE remains a factor to be evaluated, not necessarily for its role in the etiology but for its significance in the chronicity of the disease.

Nonspecific Dermatitis.—In *nummular* dermatitis, no relationship was readily apparent between serum IgE levels and age, duration of dermatitis, or extent of cutaneous involvement.

Our findings support the statement by Krueger et al[22] that normal IgE levels are present in patients with nummular eczema. They studied 26 patients, including five children less than 15 years of age, who had moderate to severe chronic involvement with nummular dermatitis. The children had levels within the normal range for their age. Among the values for the 21 adults, 4 were greater than the normal upper limit of 500 ng/ml, and 2 of those greater than 1,000 ng/ml. They found significantly lower IgE levels in the group with nummular dermatitis than in a group with atopic dermatitis. In their opinion, the difference in IgE elevation established the two conditions as separate entities.

Normal serum IgE values have been reported from four cases of nummular dermatitis[12] and also from two cases wherein atopic dermatitis had resolved 49 and 22 years prior to the onset of nummular dermatitis.[23] Gurevitch et al[10] found an elevated geometric mean serum value of 2,218 ng/ml in three patients with nummular dermatitis; however, all of them were thought to have atopy.

Gurevitch et al[10] described 15 cases that they called eczematoid dermatitis, in which atypical eruptions occurred in adults who had no personal or family history of any atopic disorder. This group included two patients with generalized exfoliative dermatitis, one patient with generalized prurigo nodularis, and one patient with papulosquamous facial eruption. The remainder had eczematoid eruptions of varying extent. Six of the 15 patients had serum IgE levels greater than 2,350 ng/ml. The geometric mean serum IgE level was 1,348 ng/ml in the total group. In their study, the geometric mean serum IgE level of pooled sera from 51 nonatopic patients was 644 ng/ml. They did not consider the mean serum IgE level of 1,348 ng/ml to be significantly elevated. They concluded that an elevated serum IgE level may provide a helpful clue to the presence of atopy in unusual, adult-onset, eczematous disorders. In contrast, our data suggest that serum IgE is often elevated in cutaneous disease and therefore cannot be used alone to identify an individual patient with atopy. Analysis of sex, age, duration, and extent of cutaneous involvement failed to reveal any readily apparent relationship of these factors to serum IgE levels.

Dyshidrotic Dermatitis.—Our data suggest that elevated serum IgE levels occur in dyshidrotic dermatitis patients who have no evidence of atopy. The patient with the highest serum IgE level, 21,271 ng/ml, had no personal or family history for atopic disease. In these 19 cases there was no readily apparent correlation between serum IgE levels and age, sex, duration of disease, or extent of disease (ie, hands, feet, or both).

Gurevitch et al[10] discussed eight patients with a dyshidrotic eruption whose geometric mean serum IgE value was 570 ng/ml. All the patients

had a personal or family history of atopy, but none had current or past cutaneous manifestations of atopy other than the vesicular eruption of the palms, soles, or both. They found that two of the eight patients had serum IgE levels greater than 4,700 ng/ml; an additional patient had a level greater than 2,350 ng/ml. Only one of these three patients had a history of hay fever or asthma, a 14-year-old girl who had asthma and a dyshidrotic eczema of the hand for one month. These authors concluded that all eight cases could be considered as variants of atopic dermatitis with limited skin manifestations. Two other cases of dyshidrotic dermatitis were reported as having normal serum IgE levels,[12] and an additional case had a level of 1,548 ng/ml.[13] Our results suggest that dyshidrotic dermatitis is unrelated to atopic dermatitis, since the median and geometric mean levels from our 16 nonatopic patients were much lower than the levels from the atopic dermatitis group.

Dermatosis

Psoriasis.—Corresponding to the geometric mean level of 175 ng/ml in our 75 nonatopic patients are the geometric means 362 and 846 ng/ml reported in the literature.[9,10] Six reported cases had levels ranging from 61 to 410 ng/ml. The elevation of the mean serum IgE level in a group of 32 patients was not considered statistically significant[12]; and the mean level of 838 in a group of 51 patients was compared with 394 ng/ml in normal controls.[13]

Among the nonatopic patients, five with psoriatic arthropathy had significant elevation of IgE concentration and five with pustular psoriasis did not (Table 2).

Urticaria.—The three patients with an atopic background had IgE concentrations of 22,362 ng/ml (hay fever), 2,321 ng/ml (asthma), and 6.1 ng/ml (hay fever). Among 36 patients with chronic recurrent urticaria, 3 had dermatographia in extreme degree; their IgE values were 33, 596, and 615 ng/ml. The cause of the chronic urticaria in these 36 cases was uncertain, although penicillin was suspected in 3 cases. The urticaria had acute onset and brief duration in five cases. Three of them were related to penicillin ingestion (715, 1,194, and 3,231 ng/ml) and two were attributed to infection of the upper respiratory tract (100 and 3,231 ng/ml). Four patients had chronic recurring angioedema involving the facial and laryngeal tissue (16, 74, 145, and 561 ng/ml). One patient, who had cold urticaria of an acquired nonfamilial type and also a history of hay fever, had a serum IgE level of 22,362 ng/ml. One nonatopic patient with delayed pressure urticaria had a level of 2,484 ng/ml.

The geometric mean IgE concentration was 317 in our 44 urticaria patients without atopic diathesis and 172 ng/ml in 34 cases reported by Juhlin et al,[8] of which 17 were acute and 17 were chronic. In our group, seven of the 44 had levels greater than 1,000 and 12 others had levels greater than 500 ng/ml, but none of our patients with marked dermatographia or angioedema had significantly elevated serum IgE levels.

In 37 patients with urticaria described by Wüthrich et al,[12] the mean serum IgE was not significantly elevated; but when a definite antigen could be incriminated, the IgE concentration tended to be higher. The 12 patients described by Graul et al[13] had a mean of 507 ng/ml, that was compared with a mean of 163 ng/ml in 100 normal controls. Four other cases reported had normal levels.[23] As an overall group, our urticaria patients had a significantly elevated median serum IgE level; however, the pa-

tients with chronic urticaria, including those with marked simple dermatographia or chronic angioedema, did not have markedly elevated serum IgE levels. We agree with Warin and Champion[33] that these disorders are not closely associated with atopic disorders, as defined by the serum IgE level.

Acne Vulgaris.—Our 11 patients with acne vulgaris but no atopic background had a geometric mean serum IgE level of 109 ng/ml; and 56 cases reported by others also had a normal mean.[8,10,13] Seven of our patients had severe conglobata acne, and one of these had a significantly elevated level (4,906 ng/ml), which presumably was related to his atopic status.

Gurevitch et al[10] reported a geometric mean serum level of 768 ng/ml in 52 acne patients. But the 19 with an atopic background had a mean of 1,208, and the 33 without it had a mean of 592 ng/ml. As we found in comparing our atopic and nonatopic acne patients, this was a significant difference. In contrast, however, our nonatopic patients had levels that were not significantly elevated above the normal range. Signs of or a history of atopy were present in four of their six cases with levels greater than 2,350 ng/ml. They postulated, therefore, that elevated IgE levels may reflect atop even in the absence of obvious allergic diseases or, alternatively, that elevated IgE levels in some cases may be unrelated to atopy.

Alopecia Areata.—The significantly elevated levels in nonatopic patients contrast noticeably with the six normal levels reported by others.[8,12,13] The nine patients with alopecia totalis whose history was negative for atopy had a median serum IgE level of 155 ng/ml.

Pityriasis Rubra Pilaris.—Despite the small size of the sample, the median and geometric mean levels were significantly elevated, appreciably more so than in the psoriatic group.

Lichen Planus.—In this small group, the serum IgE levels were not significantly elevated. Two patients described by others had normal serum IgE levels.[10,12]

Tinea Pedis.—Jones et al[34] have stated that atopic individuals who have either allergic rhinitis or bronchial asthma, or who have a history of these conditions, have an increased tendency to develop this chronic dermatophytosis. Our 15 patients with tinea pedis had serum IgE levels that did not differ significantly from those of normal controls.

CONCLUSION

Our data clearly indicate a strong correlation between elevated serum IgE levels and atopic dermatitis. The cases of acquired generalized dermatitis that had very high serum IgE levels may represent a new entity in adult, nonatopic individuals. The major finding in this study, however, is that serum IgE levels are significantly elevated in the majority of the common dermatitides and dermatoses. This relationship persists even after the exclusion of atopic individuals from the study groups. Cutaneous reactions of many types may cause a significant elevation of serum IgE. Our data suggest that, in the majority of the common dermatitides and dermatoses, elevated levels of serum IgE are a secondary phenomenon rather than a primary causative factor.

This investigation was supported in part by Research Grant AI-11483 from the National Institutes of Health.

Peter C. O'Brien, PhD, and Jeanine E. Ransom performed the statistical analyses.

Giant Basal Cell Carcinoma

Mary C. Curry, MD; Hamilton Montgomery, MD; Richard K. Winkelmann, MD, PhD

• **Whereas basal cell carcinoma usually is a slow-growing tumor of the head and neck region, we have observed, over a 20-year period, three large, unique basal cell tumors of the back that were distinctive and presented clinical and histologic problems in diagnosis. They commonly formed exophytic, vegetative, flesh-colored to red, sessile plaques up to 20 cm in diameter. Ulceration was the principal feature of a fourth tumor, which destroyed the skin of the entire lumbar area and invaded the muscle. Regional-node metastases from this tumor showed basal cell carcinoma. Histologically, all the primary lesions were adenoid basal cell carcinomas with mucinous stroma. Histochemistry in two cases demonstrated minimal respiratory enzymes and no special esterolytic or lysosomal enzymes. Surgery was curative in three of these cases of rare, giant variant of basal cell carcinoma of the skin.**

(*Arch Dermatol* 113:316-319, 1977)

Basal cell carcinoma is one of the tumors most frequently seen by dermatologists, and many histologic and clinical variants have been noted. Recently, we have compiled four cases of giant basal cell carcinoma of the back, seen in the course of 20 years.

REPORT OF CASES

CASE 1.—A 72-year-old man came to the department of dermatology for removal of a tumor that had been on the lower part of his back for at least ten years (Fig 1, top). When first noticed, the lesion had been about the size of a dime, and it had grown slowly. In the last year, it had begun to weep foul-smelling fluid and to bleed with minimal trauma. The lesion produced no other symptoms, and the patient was in good general health.

Examination revealed a plate-shaped (12 × 8 × 2 cm) friable, weeping tumor of the right lumbar area. There were telangiectasias at the base of the lesion, but the surrounding epithelium was intact.

Other physical, radiologic, and laboratory findings were normal, except for mild iron-deficiency anemia.

The lesion was completely excised to the fascia, and a split-thickness graft was applied.

CASE 2.—A 67-year-old man came to the department of dermatology for removal of a large tumor that had been on his back for 25 years. The lesion had grown slowly, but in recent years, it had begun to bleed easily. The patient had been in good health and had sought no medical advice.

Examination revealed a fungating, friable sessile tumor (8 × 12 × 12 cm) in the midlumbar area. The epidermis to the base of the lesion was intact. The surrounding subcutaneous tissue was indurated, but there were no visible satellite lesions.

Physical, radiologic, and laboratory examinations revealed no other abnormalities except for iron-deficiency anemia.

The lesion was completely excised to the fascia, and a pedicle graft was applied. Two years later the patient was treated for a small recurrence in the flap. Subsequent follow-up examinations gave negative findings.

CASE 3.—A 72-year-old woman came to the department of dermatology for definitive medical advice concerning a tumor present on her back for 20 years (Fig 1, center). The lesion had grown slowly at first; but in the last several years, it had begun to grow more rapidly, to bleed easily, and to weep serous fluid, though otherwise it was asymptomatic. One physician had told her it was cancerous; another had said it was not. The patient was in good general health.

Examination revealed an erythematous, friable, fungating tumor, 15 × 12 × 2 cm, which appeared to burrow laterally under the skin. The epidermis was intact to the base of the tumor. No satellite lesions were apparent.

Other physical, radiologic, and laboratory examinations disclosed no abnormalities except iron-deficiency anemia.

The lesion was excised completely to the fascia, and a split-thickness graft was applied. There was no recurrence at one-year follow-up.

CASE 4.—A 43-year-old woman came to the Mayo Clinic because of a mole on her back that had been present 20 years. Seven years before her visit, it had begun to grow at an accelerated rate, to ulcerate, and to bleed. Surgical removal had been suggested at that time, but the patient had refused. The lesion had continued to enlarge and to weep foul-smelling, purulent material; and the patient had begun to isolate herself from family and friends. She had been amenorrheic for the past year and had lost 7 kg.

Physical examination revealed a necrotic, purulent ulcer, 26 × 28 cm, on the midback at the L2-4 level (Fig 1, bottom), seeming to penetrate into the deep fascia overlying the vertebrae. The lesion had a discrete, sclerotic, slightly elevated margin. Within the ulcer were scattered dark-purple indurated nodules. There were hyperplastic nodes (1 cm) in the right inguinal and right axillary regions. Mucous membranes were pale.

A chest roentgenogram revealed cardiomegaly but no evidence of pulmonary lesions. The hemoglobin was 4.2 g/100 ml and the hematocrit, 15.3%. Iron studies showed iron-deficiency anemia. The cardiomegaly and hematologic abnormalities resolved after a 7-unit transfusion.

Radiologic studies of the bones showed no metastasis. Liver function was normal, although a liver-spleen scan showed hepatomegaly without focal defects in uptake.

Serum thyroxine, creatinine, and electrolyte values were normal. Serum protein electrophoresis revealed decreased albumin. Delayed hypersensitivity skin tests were positive for mumps only (5-mm induration).

Cultures of the ulcer grew numerous anaerobic and aerobic organisms, including *Escherichia coli*, corynebacteria, β-hemolytic streptococci of group D, *Bacteroides fragilis*, *B melaninogenicus*, and *Staphylococcus epidermidis*. No acid-fast organisms or fungi grew out. Cultures of the blood for aerobic, anaerobic, and acid-fast bacteria and fungi were negative.

Biopsies of the ulcer margins (both upper and lower) and the central nodules, and of the right axillary and right inguinal hypertrophic lymph nodes were done.

Dressings wet with potassium permanganate were applied to the ulcer. Because it was not resectable, 2,100 rads of radiation were directed to it in divided doses. The patient was dismissed with a prescription for 50 mg methotrexate, administered intramuscularly every week.

At follow-up in October 1973, metastasis to the left ribs was noted, and x-ray treatment was given.

In March 1974, metastasis to the right axillary node was verified as basal cell

carcinoma by excision biopsy findings.

The ulcer itself seemed to be slowly healing. In June 1974, there was a 2-cm margin of healing around it, and biopsy of the margin showed fibrosis.

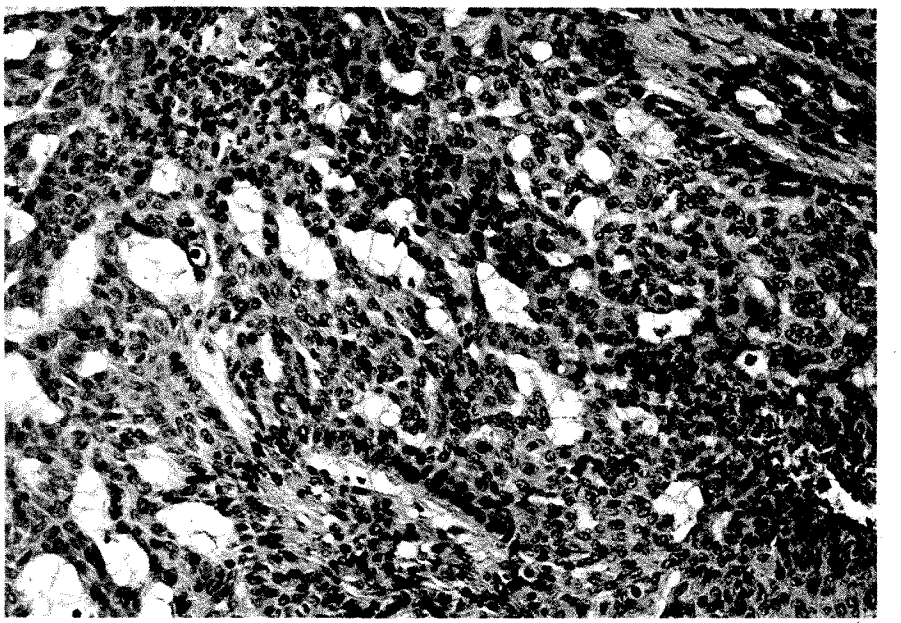

Fig 2.—Case 1. Basaloid character of tumor cells with peripheral palisades of cells and well-developed vascular stroma (hematoxylin-eosin, original magnification ×170).

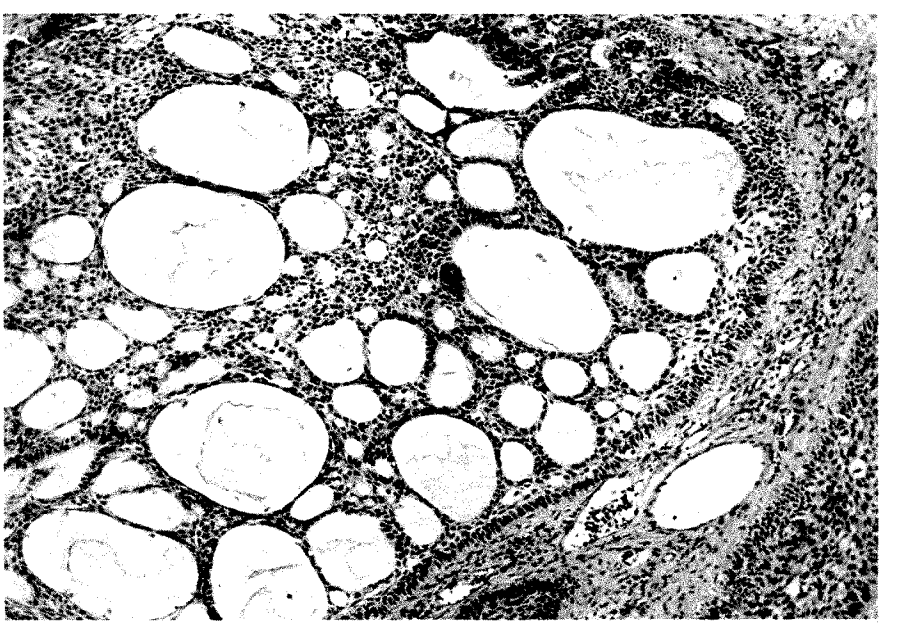
Fig 3.—Case 2. Characteristic cystic-mucinous degeneration extending to periphery of tumor (hematoxylin-eosin, original magnification ×70).



In January 1975, the tumor was noted to have progressed. Pulmonary metastasis was suspected. Administration of methotrexate was replaced by a cyclic program of prednisone (Deltasone) and cyclophosphamide (Cytoxan), each given at the rate of 50 mg daily on the same five days during one week per month. The patient has continued to do poorly and presently is bedridden.

LABORATORY INVESTIGATION
Histochemical Methods

Tissue from all four tumors and the metastatic lymph nodes in case 4 were stained with hematoxylin-eosin, PAS, and elastin-Giemsa.

Wedges of tissue from cases 1 and 4 were frozen immediately in liquid nitrogen. Sections were cut with a cryostat and tested for the following enzymes: acid phosphatase, alkaline phosphatase, adenosine triphosphatase, indoxyl esterase, nonspecific esterase, cholinesterase, leucine aminopeptidase, succinic dehydrogenase, nicotinamide adenine nucleotide dehydrogenase, and glycogen phosphorylase.[1]

Microscopic Observations

The histologic features of the first three tumors are identical. The tumors consist of strongly basophilic oval or slightly elongated cells with scant cytoplasm. The nuclei are hyperchromatic. There are five to ten mitoses per high-power field. These cells are arranged haphazardly in compact strands, sheets, or islands bounded by a single layer of palisaded cells (Fig 2). The larger islands have areas of cystic degeneration, some of which are so extensive as to give a Swiss cheese appearance to the tumor (Fig 3). At the periphery of the lesion, these tumor masses can be seen to be coming directly off the basal cell layer. The tumors extend down to the level of the middermis (Fig 4). The fibrous stroma contains a well-developed vascular network.

The histologic features of the fourth case are more consistent with morpheiform basal cell carcinoma. Small sheets and strands of oval basophilic cells are sandwiched in a dense fibrous stroma scattered throughout the dermis and into the subcutaneous tissue (Fig 5). The tumor can be seen to attach to the basal-cell layer of the epidermis. Larger islands of cells do show cystic degeneration. There are 10 to 20 mitoses per high-power field in this tumor.

Metastases in the inguinal lymph nodes show an identical pattern of small islands of immature basaloid cells sandwiched in dense fibrous stroma that occupies and destroys the major part of the nodes (Fig 6). There is no evidence of maturation or differentiation toward squamous cells.

Histochemical studies of tumors from subjects 1 and 4 gave results consistent with basal cell carcinoma. There was mild generalized activity of the respiratory enzymes, as is usual in basal cell carcinoma. There was no acid phosphatase activity. Alkaline phosphatase, adenosine triphosphatase, and leucine aminopeptidase activity characterized the vascular stroma and was associated with the endothelial cells of the vessels and vascular stroma.

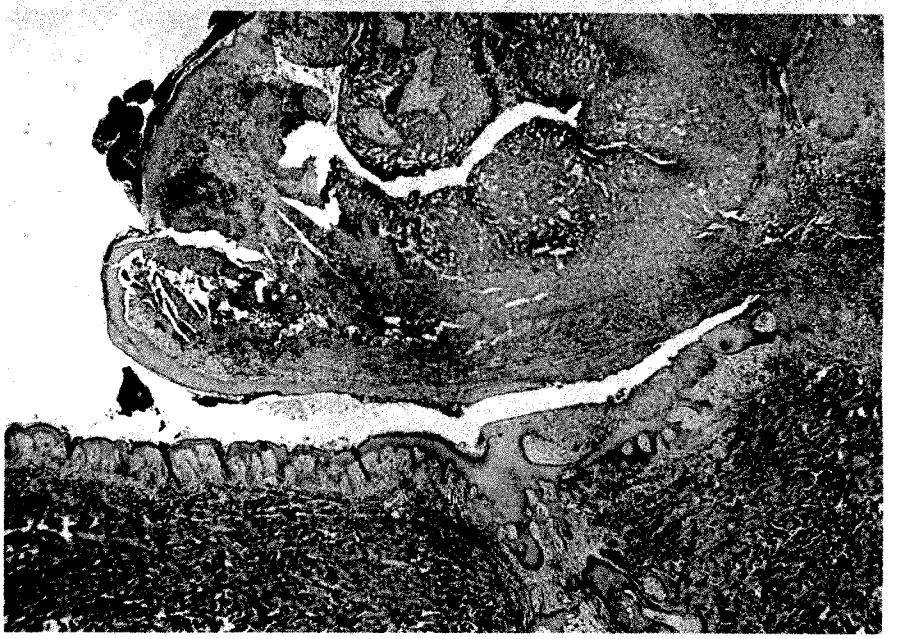


Fig 4.—Case 1. Tumor grows directly off basal area and remains exophytic (hematoxylin-eosin, original magnification ×20).

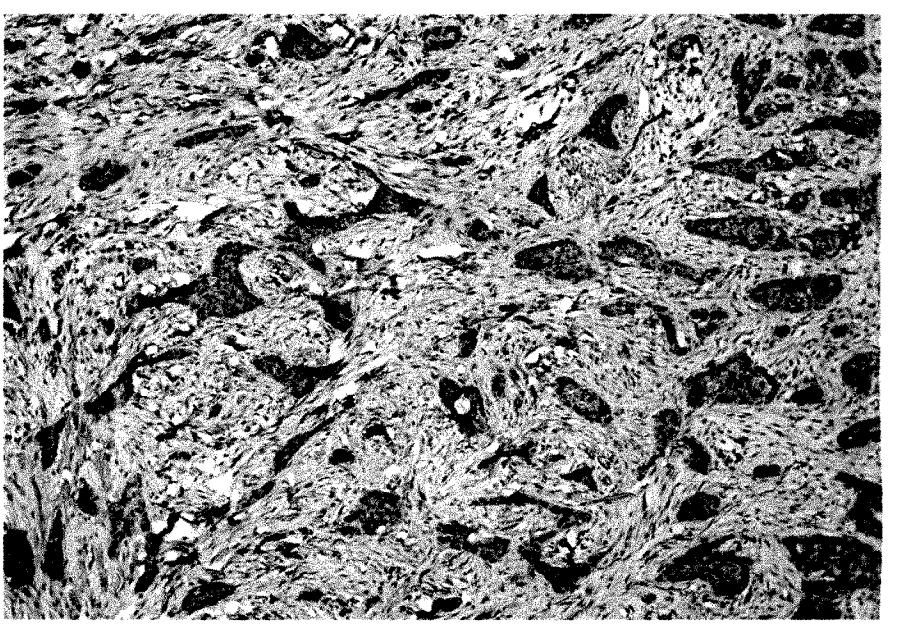
Fig 5.—Case 4. Rodent ulcer has almost morpheiform character at edges (hematoxylin-eosin, original magnification ×70).



COMMENT

Basal cell carcinoma is the most common skin cancer in the white population. It is most frequent on the head and neck and is often multiple. Ultraviolet light, exposure x-ray, exposure arsenic ingestion and genetic factors are important in its etiology; but in most cases no cause can be found. It is generally a cancer of the middle to later years.

One may classify basal cell tumors by clinical morphological findings. Nodular basal cell carcinomas are firm and are raised from the surrounding skin. They may or may not be ulcerated or hyperkeratotic. Superficial basal cell carcinomas, however, are flat, eczematous, and hyperkeratotic. They may have a well-demarcated, papular, pearly border. Many are pigmented. Fibrous basal cell carcinomas include the morpheiform basal cell carcinoma and the fibroepithelioma of Pinkus. These are very firm plaques or papules that often are mistaken for scars or benign fibrous growths.

Further classification of basal cell carcinoma may be made on the basis

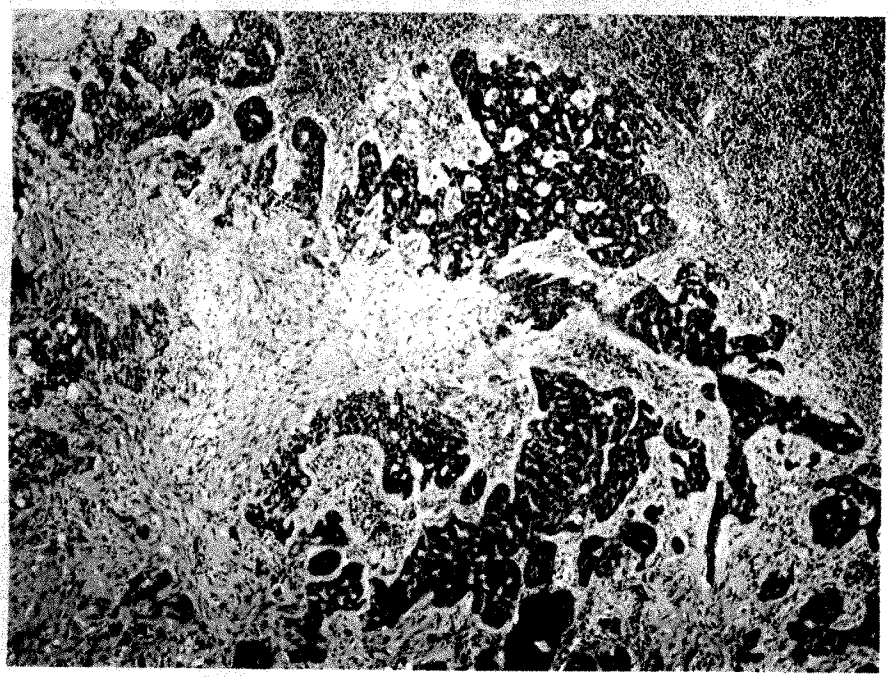


Fig 6.—Case 4. In lymph node, basal cell carcinoma similar to primary carcinoma (hematoxylin-eosin, original magnification ×64).

of histopathological findings. Solid tumors are masses of basal cells with minimal connective-tissue stroma. Cystic tumors show regional cystic degeneration. Mucinous tumors contain much mucin and myxoid elements in the stroma. Keratotic lesions afford some minimal evidence of differentiation, usually toward pilar structures. Bowenoid lesions show clear-cut malignant changes and cellular pleomorphism. Any form of basal cell carcinoma may manifest some tendency toward pilar, eccrine, apocrine, or sebaceous differentiation.

Large basal cell carcinoma occurs, but quite uncommonly. Three types of basal cell carcinoma are recognized as follows: (1) superficial, (2) rodent ulcer, and (3) vegetative. Some of these are associated with ingestion of arsenicals. Arsenic-induced tumors present a distinct clinical appearance of multiple superficial spreading lesions, mostly on the trunk. These may be asymptomatic and may become very large before the patient seeks any attention. Occasionally, nodules or internal malignancy develops.

More dramatic are those basal cell carcinomas that metastasize or are so invasive locally as to destroy vital structures. These are rare—fewer than 100 cases have been reported.[2,3] Eighty-five percent of them occur on the head and neck. They are slow-growing, but relentless and recalcitrant to radical surgery and irradiation. The "ulcus terebrans" variety may involve most of the scalp and invade, through bone, into the leptomeninges.[4-7] Lesions on the face may invade through the orbit, sinuses, or large vessels of the neck. Much less common are large invasive lesions of the back and extremities. All are ulcerative and penetrate deeply.

Metastasis occurs most frequently in regional lymph nodes, and next most often in the lungs. Such developments from tumors of the head and neck may be related to implantation. The frequencies of liver and bone metastasis are almost equal.

The lesion in case 4 is a giant rodent ulcer. It was an isolated, long-standing tumor, ulcerative and invasive from onset. The patient had no history of arsenic ingestion. At the time she sought medical treatment, the lesion was inoperable and metastasis to regional lymph nodes had occurred. During the course of observation, bony metastases were observed. On the patient's last visit, pulmonary metastasis was suspected. The tumor has been resistant to irradiation and chemotherapy, though some improvement occurred with methotrexate.

Cases 1, 2, and 3 are unique, and we could find no similar tumors in the English literature. Duperrat's vegetative basal cell carcinoma[8] and Degos' forme bourgeonnate et vegetante[9] may be similar lesions. Petres and Hagedorn[10] included a similar-appearing tumor in their discussion of surgical management of large epitheliomas but did not mention its histologic type. Characteristically, the lesions described in the literature have been exophytic and verrucous. They are contained within the dermis. Recurrences after excision have been at the periphery, not under the flaps or grafts. Except for mild stable iron-deficiency anemia, these tumors have not affected the health of the host. The inflammatory response to them is not greater than for any other basal cell carcinoma. Our cases indicate that these lesions are isolated and not associated with other skin or visceral malignancy. The patients have no history of arsenical therapy. All do come from small, rural Midwestern communities. The distinct biologic nature of these tumors may be related to the characteristics of the tumor stroma,[11] as in fibroepithelioma; but the lesions do not show such a relation clearly. These rare tumors need to be recognized and treated early.

Pathologic Findings in Human Scabies

Nilda Fernandez, MD; Antonio Torres, MD; A. Bernard Ackerman, MD

• **The histologic findings in the papular, vesicular, nodular, and Norwegian variants of scabies have in common a superficial and deep perivascular mixed inflammatory cell infiltrate of lymphocytes, histiocytes, and numerous eosinophils. A spongiotic vesicle occurs in the papulovesicular type, a dense cellular infiltrate in the nodular type, and a hyperkeratotic psoriasiform dermatitis in the Norwegian type. Eggs, larvae, and adult mites are abundant in the cornified layer of Norwegian scabies, are practically never found in biopsy specimens from lesions of nodular scabies, and are discovered only episodically in papulovesicular lesions.**
(*Arch Dermatol* 113:320-324, 1977)

Within the past few years there has been an explosion of cases of scabies in the United States.[1] Because the mite, *Sarcoptes scabiei*, evokes a variety of cutaneous lesions (macules, papules, vesicles, pustules, bullae, nodules, and scaling plaques) in different body sites, scabies can be confused with many other skin diseases. Biopsy specimens from cases of scabies sent to our pathology laboratory are rarely accompanied by notation of the clinical impression of scabies, but rather by diagnoses of dermatitis herpetiformis,[2] drug eruption, or insect-bite reaction. Pathologists often misread the histologic changes of scabies as those of drug eruptions, erythema multiforme, and even malignant lymphoma.[3] The present study was undertaken to alert dermatologists and pathologists to the pathologic changes of scabies.

MATERIALS AND METHODS

The material for this study came from biopsy specimens submitted to the Dermatopathology Laboratory of the New York University School of Medicine during the 22 months between July 1973 and May 1975. There were 26 cases of papulovesicular scabies, ten cases of nodular scabies and three cases of Norwegian scabies. For the diagnosis of the papulovesicular and Norwegian types of scabies, we required finding a mite or its eggs in the cornified layer; for the nodular type, other criteria obtained, namely, characteristic clinical lesions in a patient with scabies proven by positive scrapings from other papular or vesicular lesions. All specimens were processed in the routine fashion and were stained with hematoxylin-eosin. In most instances, step sections were made through the entire specimen.

RESULTS

The papulovesicular type of scabies, the most common manifestation of the infestation in human skin, typically showed a superficial and deep perivascular mixed inflammatory-cell infiltrate of lymphocytes, histiocytes, and numerous eosinophils (Fig 1). The eosinophils particularly were scattered among collagen bundles at all levels of the dermis. Occasionally, the inflammatory-cell infiltrate was found to extend into the subcutaneous fat. The overlying epidermis often showed a focus of spongiosis or spongiotic vesiculation, above which was a scale-crust composed of parakeratotic cells and homogenous eosinophilic material (serum) (Fig 2). Within this scale-crust it was possible to see the mite, egg shells, eggs with visible larvae, or feces. The papillary dermis was usually edematous. If the lesion had been excoriated, neutrophils could be found within the scale-crust and within the papillary dermis, where there were also extravasated erythrocytes. An uncommon finding was vasculitis, especially involving the blood vessels of the deep venular plexus. Here, inflammatory cells were present within the vessel wall, where there also was fibrillary eosinophilic material (fibrinoid). Infrequently, a mite could be found lodging within the cornified zone of a follicular infundibulum (Fig 3).

The papules of papulovesicular scabies are dome-shaped, pinkish-red, and range in size from pin point to 5 mm. Because of the intense pruritus, the papules are often eroded and covered by yellowish or hemorrhagic crusts, which are evidence of excoriations (Fig 4). The vesicles of papulovesicular scabies are tense and slightly elevated, being 2 to 3 mm in diameter.

We found, as others have,[4-6] that the burrows of scabies are formed principally within the cornified layer (Fig 5). Orthokeratotic and some parakeratotic cells constituted the roof of the burrow and most of the floor, but in some foci the head of the mite

extended into the spinous zone, where there often was spongiosis. The epidermis beneath the burrow was usually hyperplastic. The inflammatory-cell changes within the dermis beneath burrows were the same as in other lesions of papulovesicular scabies.

The burrow is a fine, curved, slightly elevated track 3 to 15 mm long. A small papule or papulovesicle at one end of the burrow marks the site of the mite within the cornified layer.

Nodular scabies showed dense inflammatory-cell infiltrates of lymphocytes, histiocytes, plasma cells, eosinophils, and atypical mononuclear cells (some in mitosis) arranged predominantly around thickened blood vessels throughout the dermis and sometimes around blood vessels in subcutaneous fat (Fig 6). Inflammatory cells were also present among the collagen bundles. The papillary dermis was usually thickened by coarse collagen fibers associated with increased numbers of plump, stellate, and multinucleated fibroblasts. Frequently, vasculitis with fibrinoid and inflammatory cells was present within dermal blood vessel walls. Sometimes thrombi occluded the lumina of these vessels. Extravasated erythrocytes were found in the connective tissue around such blood vessels. The overlying epidermis was usually hyperplastic and hyperkeratotic. Mites, their eggs, or excreta were rarely found in the cornified layer of nodular lesions of scabies.

Nodular lesions of scabies are firm, elevated, round or oval, and vary from bright red at the outset to brownish-red and eventually to dark brown (Fig 7). Nodular lesions of scabies may persist for months and even years.[7-10]

Norwegian scabies was characterized by massive orthokeratosis and parakeratosis within and between which great numbers of mites resided (Fig 8). The mites could be seen in all stages of development: adult, larval, and egg (some containing visible larvae). Adult mites are considerably larger than larval ones. Fecal material was strewn throughout the cornified layer appearing as lumps of brown granular material. In addition, homogeneous eosinophilic material (serum) and RBCs were also seen within the cornified layer. The remainder of the epidermis was substantially psoriasiform and usually hypergranular. Foci of spongiosis, spongiform pustules, and neutrophilic abscesses (Fig 9) were seen within the spinous zone. These changes were usually found in close proximity to the mite or its eggs. Mitotic figures were usually increased in the basal and spinous zones. The papillary dermis was thickened by vertically streaked collagen oriented perpendicular to the surface of the specimen and parallel to the rete ridges, and there was an increased number of dilated, somewhat thick-walled capillaries. A superficial and deep perivascular lymphohistiocytic infiltrate with numerous plasma cells, eosinophils, and neutrophils sur-

rounded the blood vessels at all levels of the dermis, but especially the upper half. Norwegian scabies, also named "crusted scabies," is characterized by thick, scaly, crusted, whitish-yellow plaques (Fig 10).[11-17]

COMMENT

With the rising incidence of scabies, dermatologists and pathologists have been confronted with diagnostic problems regarding the gross and microscopical features of the disease. Clinically, scabies can mimic a variety of other conditions, most notably dermatitis herpetiformis.[2] Histologically, papulovesicular scabies has been misinterpreted as drug eruptions or erythema multiforme[18] and nodular scabies as malignant lymphoma.[3]

The histologic concomitants of the papulovesicular lesions of scabies are a superficial and deep perivascular lymphohistiocytic infiltrate with eosinophils, the cells also being scattered among collagen bundles at all levels of the dermis, but especially the upper half, and sometimes extending into the subcutaneous fat. The papillary dermis is usually edematous. Focal intracellular and intercellular edema may eventuate in an intraepidermal vesicle. Vasculitis occurs in some instances. These histologic changes of papulovesicular lesions of scabies are indistinguishable from those of other arthropod-bite reactions, such as mosquitoes and bed bugs. The larva of creeping eruption induces histologic changes that cannot be differentiated from those produced by the mite in papulovesicular scabies and other acute arthropod reactions.

The histologic findings in papulovesicular scabies are not comparable to those of any drug eruption nor should they be confused with erythema multiforme. There are many different cutaneous histologic expressions of reactions to drugs such as urticarial, fixed, and bullous, but none of them produces the dermal and epidermal changes that are seen in papulovesicular scabies. Unlike the histologic appearance of papulovesicular scabies, erythema multiforme consists of an inflammatory-cell infiltrate of lymphocytes and histiocytes that involves the vessels of the superficial plexus only. There are practically no eosinophils or neutrophils in the infiltrate of erythema multiforme. In addition, the

epidermal changes of erythema multiforme, consisting initially of individual necrotic keratinocytes and eventually of confluent epidermal necrosis, are entirely different from the usual epidermal changes of scabies.[19]

When the dermal changes common to papulovesicular scabies, other arthropod-bite reactions, and creeping eruption are noted, the next step should be to search the cornified layer for an adult mite, its larvae, eggs, or feces. If these are not found, more sections should be made through the specimen in an attempt to find them. Unfortunately, even in a patient with scabies proven by scraping, it may not be possible to find the mite in every random biopsy specimen.

Nodular scabies (persistent nodules in scabies) is characterized by a dense superficial and deep perivascular, predominantly lymphohistiocytic infiltrate with numerous plasma cells and eosinophils. These cells are also scattered among collagen bundles. The papillary dermis is thickened by coarse collagen fibers associated with stellate and multinucleate fibroblasts. Vascular changes may be present in the form of thickened blood-vessel walls with plump endothelial cells, and there may even be vasculitis. The mite and its parts are rarely seen in the cornified layer of nodular scabies. This is not to be taken to mean that they were not originally present, but that because of the long-standing nature of these nodular lesions, the mite has been either eliminated by therapy or by scratching. The histologic features of nodular scabies favor an inflammatory, rather than neoplastic, process: the infiltrate is always more dense in the upper rather than the lower portion of the dermis, the infiltrate is mixed, the blood vessels are increased in number, and their walls are altered by thickening and sometimes by vasculitis. There are two types of malignant lymphoma with mixed-inflammatory infiltrates, namely, Hodgkin disease and mycosis fungoides. Unlike Hodgkin disease, nodular scabies does not have Reed-Sternberg cells, and unlike mycosis fungoides, atypical mononuclear cells are not present within the epidermis. The histologic differential diagnosis of nodular scabies includes long-standing granulomatous reactions to arthropod bites.

The histologic signs of papillary dermal thickening by vertically streaked coarse collagen fibers associated with numerous stellate and multinucleate fibroblasts are evidence of active fibroplasia in a lesion that has been chronically rubbed (lichen simplex chronicus, prurigo nodularis).[20] Rubbing is surely one contributing factor to the development of nodular lesions in scabies. Another factor is the special skin of the genital region that seems to respond to the mite with a more vigorous inflammatory reaction and subsequent nodule formation, rather than by papules and vesicles.

Norwegian scabies is characterized by psoriasiform dermatitis that involves the blood vessels of both plexuses and consists of perivascular mixed inflammatory-cell infiltrate of lymphocytes, histiocytes, neutrophils, plasma cells, and eosinophils. The papillary dermis is thickened by a vertically streaked collagen, another sign of long-standing rubbing. The most dramatic change involves the cornified layer, which the mites abound within. Layered in tiers throughout the cornified layer are adult mites, larvae, eggs containing larvae, egg shells, and nuggets of feces. In addition, serum and extravasated erythrocytes are frequently present within this cornified layer. Beneath the cornified layer, there are frequently spongiotic and pustular foci. In sum, the histologic changes of Norwegian scabies are unique, not to be confused with any other psoriasiform dermatitis.

Because of its extraordinarily varied clinical and histologic characteristics, syphilis has often been termed the great imitator. The same can be said for scabies.

William George, MD, contributed two cases of Norwegian scabies, and Roger Stewart, MD, submitted five cases of nodular scabies.

Bullous Disease of Childhood

Report of a Case Demonstrating Antibasal Cell Antibody

Edward Shmunes, MD, Suyu Shu, PhD

• This report describes a child with protracted bullous disease responsive only to high doses of steroids, who on immunofluorescent testing, consistently displays antibasal cell antibody. The child had been treated with penicillin a week prior to the development of the bullous disease. The etiologic possibility of this drug history in the evolution of the bullous disease is raised, with particular respect to recent reports of similar circulating antibody in drug reactions.

(*Arch Dermatol* 113:325-327, 1977)

Childhood bullous diseases have given rise to nosologic confusion due to their varying response to sulfones and sulfapyridine, usually negative results from immunofluorescent studies, and histologic patterns no more characteristic than subepidermal bulla formation.[1] Jordon et al[2] suggested the name "benign chronic bullous dermatosis of childhood" as perhaps a more fitting designation than either bullous pemphigoid of childhood or bullous dermatitis herpetiformis of childhood, when this constellation of clinical and laboratory tests occurred in a child with bullous disease.[2] A shortened form "bullous disease of childhood" has persisted and appeared in society transactions.[3] In 1974, Bean and Jordon[4] included this entity along with bullous pemphigoid, dermatitis herpetiformis, and pemphigus, labeling this group "chronic nonhereditary blistering disease in children." The following case report describes a child with protracted bullous disease responsive only to high doses of steroids, who on immunofluorescent testing, consistently displays antibasal cell antibodies.

REPORT OF A CASE

A 5-year-old boy developed a generalized bullous dermatitis one week following a penicillin injection in July 1973. The penicillin had been given by another physician because of a severe purulent dermatitis of his legs characterized by boils that had been spreading rapidly over a seven-day span. The child had previously been in good health.

Physical findings at the time of hospital admission revealed the patient to be febrile, uncomfortable, and covered with tense bullae over the arms, legs, trunk, face, and scalp. The lower left leg was covered with a confluent purulent crust, which at its periphery showed many tiny, tense bullae. The satelliting phenomenon was evident around resolving older lesions and in other areas as well. Mucosal surfaces were spared (Fig 1).

Results of the following laboratory studies were within normal limits: sickle cell preparation, the VDRL test for syphilis, antistreptolysin titer, blood culture, urinalysis, hemoglobin, glucose 6-phosphate dehydrogenase, hematocrit, and stool examinations for ova and parasites. The WBC count was elevated at 11,000/cu mm and showed 71 neutrophils, 20 lymphocytes, 4 monocytes, and 5 eosinophils on differential cell count. Serum protein electrophoresis showed slightly elevated α_2 and γ-globulin fractions. Bacteriological culture from a purulent lesion on the leg produced mixed growth of a coagulase positive *Staphylococcus*, *Enterococcus*, and *Proteus vulgaris*. Viral cultures of blister fluid failed to produce isolates in three host systems.

A biopsy specimen of an early bullous lesion from the back revealed a subepidermal vesicle showing a mixture of many neutrophils, eosinophils, and lymphocytes. The underlying dermis showed prominent perivascular infiltrate around capillaries and veins.

Course

The patient failed to respond to tub baths and systemic antibiotics. His condition was finally controlled and he was discharged on a regimen of 40 mg of prednisone daily.

Attempts to taper prednisone dosages slowly, 5 mg weekly, were met with flares of bullae, particularly on the legs at ranges at or below 30 mg daily. Attempts to slowly switch to alternate day therapy were also met with similar flares. During periods of

good control, he was placed on separate trials of dapsone, 50 mg daily, and sulfapyridine, 1 gm daily, with new efforts made to reduce prednisone dosage. Neither sulfapyridine nor dapsone at the dosages given altered his need for prednisone and during the first year, levels of 50 mg daily were necessary to achieve control. Poor social conditions resulted in suprainfection with β-hemolytic streptococci on two occasions, necessitating prophylactic penicillin therapy.

Oral administration of erythromycin was used initially, but oral administration of penicillin was given by another physician with control of the secondary infection without a resultant flare in the bullous disease. By July of 1974, the child was able to be tapered down to 10 mg of prednisone daily and in June of 1975, prednisone was discontinued without exacerbation.

Fig 1.—Older bullous lesion with satelliting.

Immunofluorescence Studies

A serum specimen was submitted for indirect immunofluorescence during the initial hospitalization. This was repeated along with direct immunofluorescent studies from both involved and uninvolved skin five months later. The direct immunofluorescent testing included testing for specific deposits of IgG, IgA, IgM, and C4.

Results

The initial indirect immunofluorescent with patient's serum on monkey esophagus sections revealed only a trace of basal cell antibody. On repeat examination five months later and while receiving 50 mg of prednisone daily, the child had a basal cell antibody titer of 1:20. This pattern of staining is shown in Fig 2. There was no basement membrane or intercellular fluorescence as in cases of bullous pemphigoid and pemphigus. Direct immunofluorescent studies of both involved and uninvolved skin failed to reveal any fluorescent patterns.

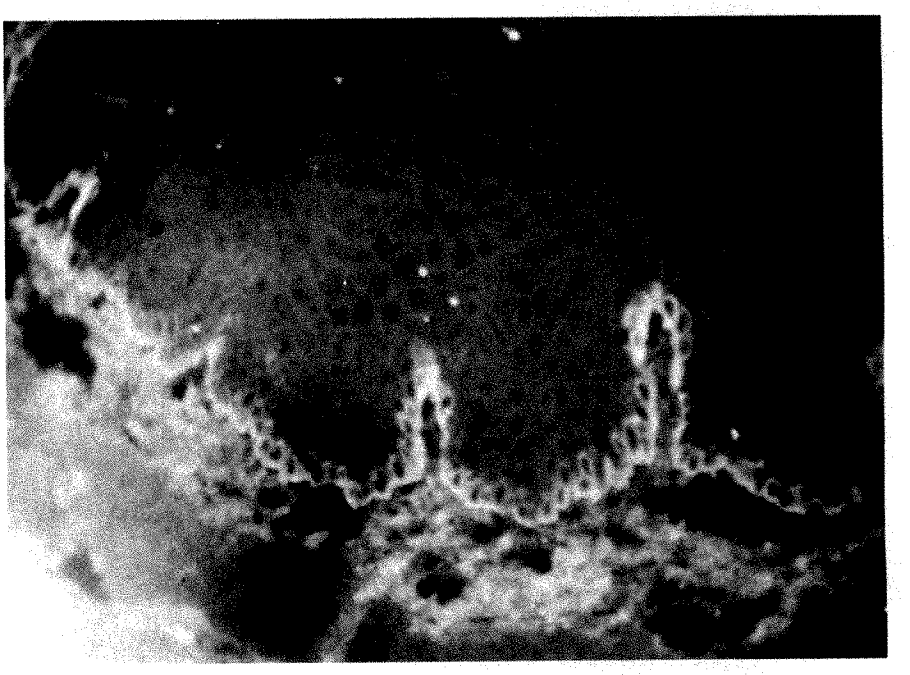

Fig 2.—Antibasal cell fluorescence pattern in patient's serum.

COMMENT

Immunoglobulin deposits in and/or on basal cells of skin have been reported on direct immunofluorescent study in drug related eruptions. Stein et al[5] reported basal cell immunofluorescence in drug induced toxic epidermal necrolysis in two patients due to penicillin and chloropromazine, respectively. Shelley et al[6] demonstrated intercellular fluorescence in the basal cell layer and the two to three adjacent suprabasilar cell layers in a patient with a bullous fixed drug eruption due to phenolphthalein. In both reports no circulating antibasal cell antibody could be detected by indirect immunofluorescence. It is possible that the direct immunofluorescence observation may represent deposits of immunoglobulin in this area secondary to the drug reaction process rather than antibody to the basal cell layer. The failure to detect circulating antibody in these instances is noteworthy.

Fellner and Prutkin[7] reported indirect immunofluorescent studies demonstrating circulating epithelial intercellular antibodies in two patients with morbilliform eruptions due to penicillin. More recently, van Joost[8] described that in 35 cases of drug reaction examined, 7 had circulating antibodies reactive with basal cells of skin of both human and guinea pig with the exception of 1 that did not react with human skin. Direct immunofluorescence tests performed on skin biopsies in four cases revealed in vivo bound immunoglobulins and complement in and/or on basal cells in the erythematous area only in one case

that had the highest titer of demonstrable antibasal cell antibody in the circulation.

In 1974, van Joost et al[9] also reported a case of a well documented drug induced skin reaction caused by phenylbutazone characterized by erythematous papules and nodules with some bulla formation. The duration of the reaction after stoppage of the offending drug was five weeks. The indirect immunofluorescent technique showed circulating IgG class antibodies reactive with the cytoplasm and membrane of basal cells of three different stratified epithelial substrates including guinea pig lip, monkey esophagus, and normal human skin. They also reported the circulating basal cell antibodies were able to fix complement in vitro. Direct immunofluorescent technique of lesions in their patient showed IgG deposits in and around vessel walls and some areas of the basal cell layer.[9]

In a few patients with bullous pemphigoid or pemphigus, immunofluorescent studies reveal both basal cell and basement membrane zone antibodies or intercellular antibodies, and sometimes the former interfere with the detection of the disease antibody (T. Chlorzelski, oral communication, 1975). In these cases, direct immunofluorescent studies are corroborative.

Bean et al[10] were the first to demonstrate that some children with bullous disease have circulating antibodies to the basement membrane, supporting the concept that some of these children represent a juvenile counterpart to adult bullous pemphigoid. This has been subsequently confirmed in other selected cases, though the majority of these children with a virtually identical histopathological picture fail to give positive immunofluorescent reaction.

Jablonska et al[11] demonstrated that a small portion (two of eight patients studied) may show deposits of IgA in the papillae around the lesions on direct immunofluorescence. On the eight children studied, the two with deposits of IgA were the only two children with papular lesions only, as opposed to bullous and papular lesions. Only one of the children was responsive to sulfapyridine or sulphones.[11] Thus, another small fraction of clinical bullous disease of childhood may correspond fully to the adult form of dermatitis herpetiformis.

In our patient, the indirect immunofluorescent studies were consistently positive, even on moderately high doses of steroids. The patient's clinical course has been protracted and he has been responsive to steroids only.

The demonstration of circulating antibasal cell antibody in our patient's sera, directed against monkey esophagus, is puzzling. We were unable to demonstrate auto-reactivity, or reaction with the basal cells of monkey skin. Under fluorescent microscope, the antibody appeared to be directed against cytoplasm of basal cells rather than against cell surface or intercellular area.

Though demonstration of such interior antigens has been considered questionably significant, it may bear diagnostic value in the future. The report of van Joost[8] of similar antibody in drug reactions is particularly interesting in that our patient had a history of an intramuscular dose of penicillin one week before his eruption.

With the newer information on basal cell antibodies in drug reactions, one might be tempted to classify this case report as a drug reaction. The clinical course over a two-year period as well as the clinical presentation is similar to those cases described as bullous disease of childhood. Were it not for the positive indirect immunofluorescence directed against an interior antigen that is little understood, it would remain lumped within that group. It would appear more fitting clinically to classify this case report as bullous disease of childhood.

Judging from available information, the basal cell antibodies are at least not disease specific. Their role in the process of pathogenic changes is still not clear. Clinical correlation, particularly within the group of bullous diseases of children, appears to warrant further investigation.

Pseudofolliculitis Capitis

Maj James D. Smith, MC, USA, Lt Col Richard B. Odom, MC, USA

• Pseudofolliculitis of the bearded area is a common dermatoses among black men. Acne keloidalis probably represents this same condition, but is located in the nape area. Pseudofolliculitis of the pubic area (pseudofolliculitis pubis) has been reported. We wish to report pseudofolliculitis including the entire scalp and to add the term *pseudofolliculitis capitis* for this heretofore unreported entity.

(*Arch Dermatol* 113:328-329, 1977)

Pseudofolliculitis barbae is a well recognized entity that most often occurs in the bearded area of black men who regularly shave their faces, necks, and submental areas.[1] Alexander[2] reported this same condition in a woman with familial facial hirsutism. He also reports its occurrence in the pubic area (pseudofolliculitis pubis) of a woman who shaved the area of involvement for cosmetic reasons. Acne keloidalis most likely represents this same condition on the nape of the neck.[3] Strauss and Kligman[4] reported the basic etiological factor to be a curved ingrown hair eliciting a foreign body response.

We recently have observed severe pseudofolliculitis of the scalp of four brothers and propose the term *pseudofolliculitis capitis* for this heretofore unreported condition.

REPORT OF CASES

Four black brothers, 10, 9, 8, and 6 years old, had "scalp problems" when they came to the pediatric dermatology clinic of our hospital. Two weeks prior to their clinic visit their father had shaved the entire scalp of each individual using a straight razor with shampoo as a lathering agent. There was no apparent irritation from this process until approximately one week later when the two older patients complained of tender scalps.

There was no history of scalp disease prior to or at the time the scalps were shaved. The father shaved their scalps because he felt they were not caring for their longer hair styles properly. Each had previously used the same shampoo repeatedly without apparent ill effects. None of the involved individuals had ever had their scalps shaved previously. There was no history of pseudofolliculitis barbae in the father.

The scalps of the older two individuals were edematous and slightly boggy, with myriads of erythematous papules covering the entire scalp. Each papule had a short hair embedded in its center. The hairs were coarse, tightly coiled, and in many locations both ends of the hair were anchored into the skin, thus producing a loop effect (Fig 1). A 27-gauge needle could be slipped under these loops and with minimal leverage the end from the inflammatory papule would spring free. Each had fine

Fig 1.—Scalp showing myriads of papules with ingrown hairs. Every hair is intraepidermal yet very shallow, thus, remaining visible through epidermis.

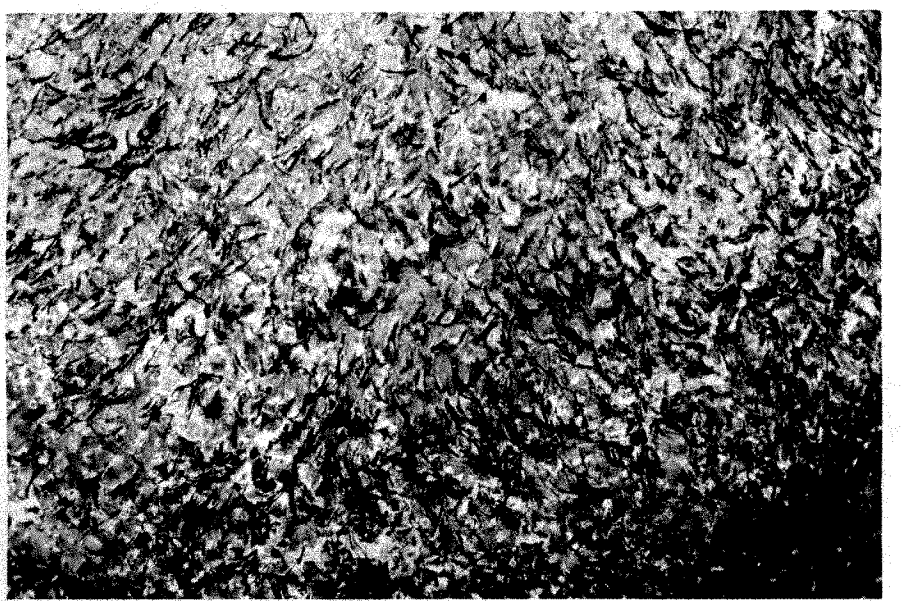

Fig 2.—Occiput area displaying fine superficial desquamation.

sheets of desquamated epidermis peeling from the occiput areas (Fig 2). A few discrete pustules were present as well as occasional small crusted areas. These two children had enlarged posterior cervical lymph nodes that were slightly tender to palpation. The two younger siblings had similar involvement localized to the occiput-nape area, but lacked lymphadenopathy.

A Wood's light examination showed no fluorescence. Results of potassium hydroxide preparations, fungal cultures, and bacterial cultures were normal.

The mother of the children was counselled regarding the pathogenesis of the problem. In view of the lymphadenopathy and crusting, each of the older patients was started on a regimen of erythromycin orally at a dosage of 250 mg three times daily. This was discontinued two days later when the bacterial cultures revealed only *Staphylococcus epidermidis*. Topical betamethasome valerate cream, 0.1%, was initiated with three daily applications. Tap water compresses were applied three times daily.

Approximately one week later the scalp of each boy was nontender. Within three weeks the individual hairs no longer penetrated the epidermis. None of the involved areas formed keloids. At three months follow-up each scalp appeared normal.

COMMENT

The pathogenesis, clinical course, and treatment of pseudofolliculitis have been amply elucidated in previous publications.[1-6] Unusual variants, such as pseudofolliculitis pubis,[2] have been documented. Certainly, black men, women, and children shave their scalps. In recent past years shaving the scalp was recommended as an integral step in the therapeutic regimen of tinea capitis. Despite these practices, it appears that pseudofolliculitis of this anatomical area has not been reported.

Several factors may have played a role in precipitating this event in the four brothers. The use of a straight razor to obtain a close shave was most likely an initiating factor. Razor shaving renders the cut end of the hair sharply pointed and facilitates reentry of the free end into the skin, thus, evoking a foreign body reaction that presents clinically as an inflammatory papule or pustule. The use of a shampoo as a lathering agent in all probability precipitated an irritant dermatitis as evidenced by the crusting and peeling scalp surface.

The fact that the patients were related certainly supports a genetic factor, as Alexander[2] proposed. We support the concept that pseudofolliculitis barbae is a genetic condition in that certain people inherit the characteristic of having curved hair follicles that produce curly and kinky hairs. These persons are thus predisposed to pili incarnati (ingrowing hairs). We have observed pseudofolliculitis barbae of a milder nature in white persons; thus, probably no race is excluded by this disease. Close shaving of the nape of these predisposed individuals initiates acne keloidalis nuchae. It seems quite reasonable that these same individuals would develop this process in the scalp, or for that matter, any site occupied by terminal hairs of a kinky, coarse character.

Pseudofolliculitis capitis is not common apparently, but the severity of the reaction in our patients warrants both medical and public awareness of its existence. One must agree with Alexander[2] that pseudofolliculitis knows no sexual or anatomical boundaries. We would add that pseudofolliculitis also respects no age limitations.

Multicentric Reticulohistiocytosis

David R. Taylor, MD

• **Multicentric reticulohistiocytosis is a rare disorder of the skin and joints that possesses distinctive histologic findings. A case is reported from shortly after its onset to a stage of resolution 4½ years later.**

(*Arch Dermatol* 113:330-332, 1977)

Multicentric reticulohistiocytosis (MR) is rare and histologically unique disorder that was initially studied by Caro and Senear in 1932.[1] They described a patient with multiple cutaneous tumors and labeled the biopsy findings reticulohistiocytic granuloma. Their further studies disclosed that the cells that comprised the tumors were reticuloendothelial in origin, since they took up injected colloidal iron. Because the lesion resembled a granuloma, it was not believed to be neoplastic.[1] The first adequately described example of the systemic form of this disease was made in 1937 by Weber and Freudenthal.[2]

Allen's study of 8,000 cutaneous tumors during World War II attests to the rarity of the disorder, since only two cases of patients were reported with histologic examples of multinucleated giant cells. He referred to these tumors as reticulohistiocytomas.[3]

In 1954, Goltz and Laymon used the term "multicentric reticulohistiocytosis" to differentiate those patients who have the full-blown syndrome of cutaneous tumors and a definite arthritis from those who do not have arthritis and have only solitary or few cutaneous lesions.[4]

Since the 1950s, a limited number of case histories have been reported. On the basis of strict diagnostic criteria, Barrow and Holubar were able to identify only 33 cases in the world literature that could qualify as examples of MR.[5] Only patients with arthritis and biopsy-confirmed, characteristic cutaneous nodules fulfilled their diagnostic requirements. The disorder is little known to rheumatologists and orthopedists, although it is listed in the *Nomenclature and Classification of Rheumatic Disease*.[6] Most reports have been in the dermatologic literature.[7-9]

REPORT OF A CASE

A 40-year-old woman was in good health until April 1971, when she developed a diffuse, small nodular eruption of the face, upper aspect of the trunk, and upper extremities. Shortly thereafter she experienced arthritis of her finger joints, wrists, elbows, and knees. The cutaneous eruption was extremely pruritic, and her joints were hot, swollen, and painful. There had been no weight loss or fever at the time of her initial complaint. Her pruritus was increased when she was exposed to sunlight. There was no history of previous skin disease or recent drug intake.

On initial examination, the patient was found to have myriads of closely set, light brown, firm, small nodules involving the frontal hairline area, the upper aspect of the forehead, and the external ears. The V-shaped area of the sternum was solid with small, 0.2-to 0.5-cm nodules that produced a cobblestone effect (Fig 1). The upper portion of the back near the neck, the nuchal zone, and the occipital area also were involved. The forearms showed scattered, slightly larger lesions, and a few nodules were observed on the dorsa and sides of the fingers, with an isolated lesion involving the paronychial areas. The outer third of her eyebrows were sparse. The finger joints were painful, red, and swollen, especially the distal interphalangeal joints. The wrists, elbows, ankle joints, and knees showed inflammation of varying degree. The knee and ankle joints were the source of her greatest discomfort: however, she remained ambulatory.

A specimen for biopsy was removed, and a dermal histopathologist's interpretation was that the findings were inconclusive, but that sarcoidosis could be considered. The tissues were then submitted to another histopathologist, and he thought that the diagnosis of a zirconium granuloma should be entertained.

There was little change in her condition until May 1972, when her joint distress and cutaneous lesions became more pronounced. A second biopsy specimen from a lesion on the elbow was suggestive of giant cell reticulohistiocytoma. The slide was then sent to another dermohistopathologist, whose findings were as follows:

This specimen shows an essentially normal epidermis. The chief change is in the rather circumscribed, but not encapsulated accumulation of multinucleated giant cells having a large amount of ground glass cytoplasm. A few smaller histiocytes and lymphocytic inflammatory cells are interspersed between the giant cells. The changes are those of reticulohistiocytoma, or multicentric reticulohistiocytosis (Fig 2).

In June 1972 her knee became extremely painful and swollen and prevented her from walking. She was hospitalized, and the results of the physical examination were as follows: temperature, 38.3 C; pulse rate, 90 beats per minute; blood pressure, 140/70 mm Hg. The dermatologic findings showed pinkish, pearly nodules involving the mucosa of the lower lip and the right corner of the mouth. The nodular eruption was observed on the head, neck, upper part of the trunk, upper extremities, and the external auditory meati.

Marked limitation of the motion of the fingers, wrists, shoulders, knees, and ankles was noted. These joints were swollen, tender, and hot; the most notable swelling was observed on the left knee. A chest film was normal. X-ray films of her hands showed soft-tissue swelling and demineralization. A rheumatoid latex fixation test and a fluorescent antinuclear antibody test were negative. Results of a complete blood cell count and uric acid study were within normal limits. Blood chemistry determinations were normal, except for a serum cholesterol level of 280 mg/100 ml. The left knee was aspirated of a thick, cloudy fluid that contained a protein level of 4.2 gm/100 ml and 44,500 polymorphonuclear leukocytes. Cultures of the aspirated fluid were negative. Results of urinalysis were normal. The ESR was 34 mm/hr, and a VDRL test for syphilis was negative. Serum electrophoresis revealed a normal pattern, and the liver scan was normal. X-ray films of the left knee showed no abnormalities, except for the suggestion of fluid in the suprapatellar space.

The patient was treated with salicylates, diazepam, and 80 mg of prednisone every other day. Her condition improved rapidly, except for the cutaneous lesions, and she was discharged in an afebrile and ambulatory state after six days of hospitalization. The patient, on her own, discontinued the prednisone treatment because of vomiting. She continuously complained of severe

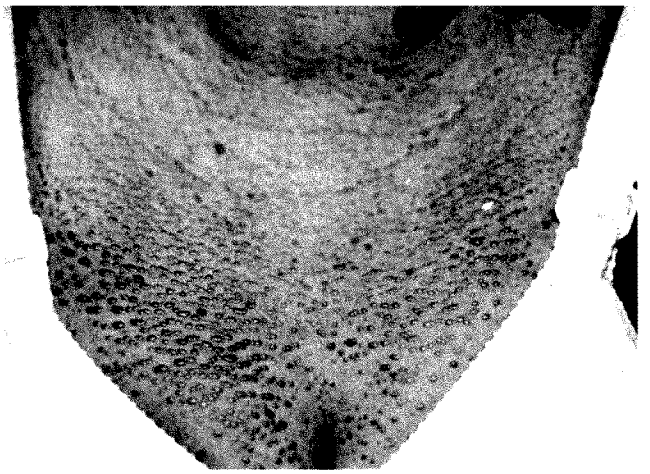

Fig 1.—Neck and V-shaped area of sternum showing numerous closely set, firm nodules in a cobblestone-like pattern.

Fig 2.—Same area as in Fig 1 showing marked clearing of eruption four years after onset.

Fig 3.—Biopsy specimen removed from lesion on elbow showing typical ground-glass-like eosinophilic cytoplasm with varying number of nuclei. Process is unencapsulated (hematoxylin-eosin, original magnification ×100).

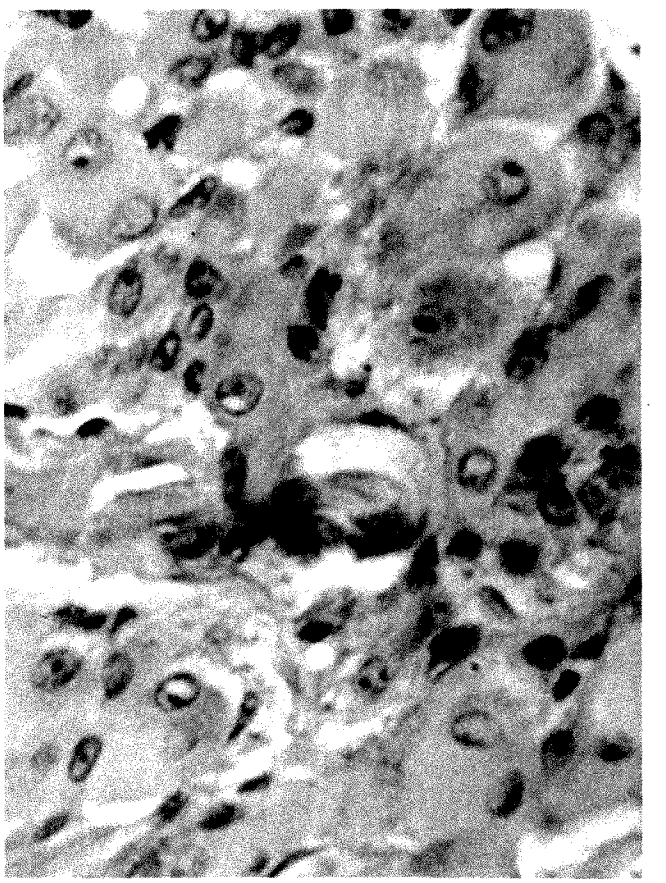

Fig 4.—Skin biopsy specimen showing large histiocytes and histiocytic giant cells with fine granular cytoplasm, vesicular nuclei, and prominent nucleoli (hematoxylin-eosin, original magnification ×400).

pruritus of her skin lesions and was given chlorpheniramine malleate orally, which gave her some relief.

One month later she sustained a myocardial infarction of the inferior wall and was hospitalized for seven days. After an uneventful recovery, she again was given prednisone to relieve her marked pruritus, along with oral chlorpheniramine. Because of increased joint distress and a flare of her cutaneous manifestations, the dosage of prednisone was increased to 40 mg per day. Following a family altercation, she took approximately 100 tablets of prednisone, but had no untoward effect as reported by her internist. The prednisone was then prescribed in smaller amounts, and an alternate-day schedule was stressed. The joint involvement gradually lessened; however, the cutaneous activity and her pruritic distress were more persistent. The joint distress was confined to mild swelling of her right ankle and was not incapacitating. In March 1974, xanthelasma palpebrarum was observed on the lids of both eyes, and a normal blood cholesterol level was determined. The xanthelasma disappeared without treatment. A second-strength purified protein derivative test was negative.

Her last examination in September 1975 disclosed no new nodules, and only a few lesions appropriate for biopsy were ob-

served on the nuchal zone. These lesions were in a state of resolution. A specimen from one was subjected to electron microscopy, and the findings were suggestive of a focal granulomatous inflammation and mild fibrosis consistent with a resolving MR. No dense bodies were seen in the tumor cells as was reported by Hashimoto and Pritzker,[9] but the specimen was from a resolving lesion.

COMMENT

The strikingly distinctive features of MR's histopathologic pattern are the presence of aggregates of histiocytic giant cells and histiocytes that can be found in the skin, synovia, and mucosa. Characteristic cellular infiltrations have even been reported in bone. The histiocytic multinucleated giant cells can be as large as 100 μ, and multiple nuclei, up to 20, can be observed. What sets the giant cells and the individual histiocytes off is the presence of a finely granular eosinophilic cytoplasm that has a ground-glass appearance. Giant cells in MR are of a foreign-body type, with the nuclei arranged in the cytoplasm haphazardly. However, peripheral alignment or central aggregation can occur. The nodular infiltrate can occupy the entire dermis and is unencapsulated. The mononuclear histiocytes constitute the other typical cellular component. They are usually oval or round, but can be irregular in size and shape. The cytoplasm is also eosinophilic and finely granular. Other cell types are lymphocytes, eosinophils, plasma cells, RBC, and fibroblasts. In younger lesions lymphocytes can form dense infiltrates. Fibroplasia may be the mode of regression because spindle cells are seen. The connective tissue stroma is pushed aside by the cellular masses, and the stroma becomes well vascularized. The epidermis is not directly invaded, but flattening and effacement of the rete ridges is noted. Histochemical studies indicate that the MR giant cells and histiocytes contain a PAS-reactive material, neutral fat, phospholipids, and iron. The PAS-positive substance, according to some investigators, may represent a mucoprotein or a glycoprotein.[5]

The clinical features of MR are visually impressive. Few or literally hundreds of small (2 to 10 mm wide) nodules may involve the head, neck, upper aspect of the trunk, and upper extremities. Typically, the fingers show nodules on the dorsal surfaces especially in the paronychial areas. The ears, bridge of the nose, and scalp are also frequent sites of distribution. The nodules range from flesh color to yellow and reddish brown. They can be pruritic (33%).[5] Mucosal surfaces have been involved in over half of the patients. Xanthelasma was reported to occur in one fourth of the patients studied by Orkin et al.[8] A leonine facies resulting from facial and paranasal nodulation can be seen in MR and could serve to confuse the disorder clinically with leprosy.

A symmetrical polyarthritis that was insidious in onset preceded the nodular eruption in nearly two thirds of the cases. Since women are affected more commonly than are men (3:1), the typical clinical picture is that of a middle-aged woman complaining of rheumatoid joint symptoms.[5] Large joints such as the knees, hips, and shoulders, as well as smaller joints, participate in the process. A clinically distinguishing feature of MR is destruction of the distal interphalangeal joints.[5] When this happens, along with destruction of other interphalangeal joints, a severely deformed hand results. Such a hand has short stubby fingers that amazingly can be stretched to their normal length. This clinical oddity has been referred to as the "accordion," or "concertina" hand.[5] One fifth of the patients have been reported to get a mutilating arthritis of the hands.[8] In four such cases, the latex, fixation tests were negative. The arthritis can be variable in its behavior, with some cases persisting, while others disappear. It does mimic rheumatoid arthritis. The cutaneous eruption cleared in one fourth of a series of patients, while it progressed in an equal percentage of patients.[8] The remainder either showed improvement or remained static. Weight loss was observed in some patients, and a small percentage became febrile. The ESR was moderately elevated, and 33% had an elevation of the serum cholesterol level.[5] Electrophoresis of serum proteins gave normal results, as did immunophoresis. Sternal marrow studies have been normal. Reactions to mumps, tuberculin, and *Candida* skin-test antigens revealed an intact delayed-hypersensitivity.[8]

If the skin is not carefully examined, MR can be easily confused with rheumatoid arthritis. The case presented demonstrates the classic findings of a serologically negative symmetric polyarthritis associated with a papulonodular eruption that is histologically distinctive. The patient also manifested the frequently associated findings of mucous membrane lesions and xanthelasma palpebrarum. The patient's cutaneous eruption, save for a few resolving scalp lesions and her joint disorder, have disappeared after it had been present for 4½ years. This is in contrast to Barrows and Holubar's report that their average patient maintained the dermatoarthritis for eight years.[5] Although the eruption has cleared, she still complains of pruritus of the previously involved sites.

It is difficult to evaluate the worth of the steroid therapy in this patient, although my impression is that it did not influence the basic pathological process. The patient is firm in her opinion that it did relieve the intense pruritus, which remained a constant complaint throughout the period of observation. Since the origin of MR remains obscure and since the majority of patients show self-resolution, the therapeutic management should be a conservative one, directed toward symptomatic relief. There is no satisfactory treatment for MR.

John D. Krafchuck, MD, and Robert W. Glotz, MD, rendered the histopathologic diagnosis.

Eruptions Due to Oral Contraceptives

Ralph J. Coskey, MD, FACP

• Three patients developed eruptions attributable to oral contraceptives. The eruptions of two of the patients resolved when the women discontinued the use of oral contraceptives. The third patient changed the type of oral contraceptive she was taking, and the eruption subsequently subsided.

(*Arch Dermatol* 113:333-334, 1977)

In 1971 I reported the cases of two women who developed an eruption secondary to the ingestion of oral contraceptives.[1] One of these patients had a papular eruption on the legs that histologically was compatible with toxic dermatitis or lymphocytic vasculitis. The other patient had a pigmented, lichenified, ecchymotic eruption on the forearms that on biopsy also showed toxic dermatitis or lymphocytic vasculitis. Both patients' eruptions resolved when the medication was discontinued. In this communication, I will describe three other women who developed dermatoses in the last three years that were attributable to the ingestion of oral contraceptives.

REPORT OF CASES

CASE 1.—A 40-year-old woman was seen on March 23, 1973 because of an erythematous, edematous, plaque-like, pruritic eruption of 13 months' duration that involved her forearms and left breast. She had been taking birth control tablets that contained 1 mg of ethynodiol diacetate and 0.1 mg of mestranol (Ovulen 21) for eight years. The eruption would always appear during the second week that she was taking the medication and would disappear at about the time she took the last tablet.

A diagnosis of a fixed drug eruption was made, and a biopsy specimen was obtained. Microscopical examination showed no important epidermal changes (Fig 1). The corium showed mild edema and a perivascular inflammatory cell infiltrate in a coat-sleeve-like fashion. The infiltrate consisted of mostly lymphocytes.

The patient discontinued the birth control medication for one menstrual cycle, during which time the eruption did not appear. However, she restarted the medication, and the dermatosis reappeared monthly until she discontinued the birth control medication after she had a tubal ligation in October 1973. The eruption disappeared, and it has not recurred since.

CASE 2.—A 20-year-old woman was seen on June 7, 1973 for a persistent, pruritic, lichenified, plaque-like eruption on the anterior aspects of her legs of two months' duration. She was taking an anovulatory agent that contained 1 mg of ethynodiol diacetate and 50 μg of ethinyl estradiol (Demulen 28). A diagnosis of a drug eruption was made, and a biopsy specimen was obtained. Microscopical examination of the tissue showed slight thickening of the epidermis, with hypergranulosis and hyperkeratosis (Fig 2). There were occasional small foci of minimal spongiosis and exocytosis, which lead to spotty parakeratosis. The corium showed a minimal perivascular infiltrate that consisted mainly of lymphocytes, a few histiocytes, eosinophils, and macrophages that contained melanin pigment granules. The findings were characteristic of lichen simplex chronicus or possibly a lichenoid form of drug eruption.

The eruption did not respond to topical application of 0.025% triamcinolone acetonide cream (Kenalog) or fluocinonide cream (Lidex). The patient discontinued the anovulatory agent in November 1974, and the eruption resolved in eight days. She was given an oral contraceptive agent that contained 1 mg of norethindrone and 0.08 mg of mestranol (Ortho-Novum 1/80) in December and has had no recurrence for the last nine months.

CASE 3.—A 20-year old woman was seen on Jan 10, 1975 because of an unremitting nummular pruritic dermatitic eruption on her neck, forearms, legs, and feet of two months' duration. Some of the lesions appeared to be infiltrated. She was taking an anovulatory agent that contained 0.5 mg of norgestrel and 0.05 mg of ethinyl estradiol (Ovral).

The eruption did not respond to treatment with 0.025% triamcinolone acetonide cream. Microscopical examination of a biopsy specimen taken on Jan 17, 1975 showed only a few small foci of mild spongiotic edema and some erosion of the lower border of the rete ridges by lymphocytes, leading to some loss of pigment into macrophages in the corium (Fig 3). The corium showed diffuse edema and a moderately heavy coat-sleeve-like perivascular inflammatory cell infiltrate that consisted largely of lymphocytes.

The patient discontinued the birth control medication on Jan 24, 1975, and continued to apply the triamcinolone acetonide cream. She was last seen on Jan 31, 1975, and the eruption had resolved.

COMMENT

There have been many cutaneous side effects reported secondary to the birth control medications. Chloasma probably is the most common.[2] If the medication is stopped, the pigmentation may or may not resolve.

Acne may improve after a woman takes an estrogen-dominant[3] oral contraceptive for three or four cycles, with an associated decrease in sebum production.[4] After the medication is taken for 12 months, a small percentage of women may develop an increase in sebaceous gland activity back to normal levels, with a corresponding flare in their acne.[4] When the medication is stopped, they may

also develop a flare of their acne due to increased sebaceous gland activity.[5]

Oral contraceptives also have been reported to cause the following cutaneous side effects: angioneurotic edema,[6] monilial vulvovaginitis,[7] photosensitivity,[8] herpes gestationis,[9] jaundice,[10] erythema multiforme,[11] hirsutism,[12] alopecia,[13] aggravation of porphyria variegata,[14] and porphyria cutanea tarda.[15-17] In addition, erythema nodosum,[18] acquired port-wine-colored marks,[19] purpura, and aggravation of hereditary hemorrhagic telangiectasia,[20] as well as telangiectasia and spider angiomas[21] have been reported.

The three cases I have described were compatible clinically with a fixed drug reaction, lichen simplex chronicus, and nummular eczema. Histologically, all three women showed changes that were compatible with a drug eruption. When the patients discontinued taking oral contraceptives, the eruptions disappeared within seven or eight days, which makes it very likely that the eruptions were due to the oral contraceptives. However, it is impossible to say if the estrogen, progestagen, or even the filler or dye in the tablet caused the dermatoses.

Amir Mehregan, MD, interpreted the histologic sections.

REM Syndrome (Reticular Erythematous Mucinosis)

Report of a Further Case or Variant of It

Kalman Keczkes, MB, ChB, MRCP, Prakash Jadhav, MB, ChB

• A 50-year-old woman had cervical lymphadenopathy, swollen and waxy-looking gums, and a diamond-shaped, reticular erythematous eruption on her back of eight years' duration. Histologic examination of the gingival tissue and skin showed round-cell infiltration around the small blood vessels and in the upper part of the dermis, and an extensive eosinophilic amorphous deposit throughout the dermis that stained with Alcian blue. The clinical and histologic features, although not identical, resembled those reported by Lischka and Orthenberger (1972)[1] and later by Steigleder et al (1974).[2,3]

(*Arch Dermatol* 113:335-338, 1977)

Lischka and Orthenberger[1] presented three cases, one male patient and two female patients, at a meeting of the Cologne Dermatological Society in 1972 with an unusual sheet-like, or net-like eruption on the chest and back. In each case, the histologic findings showed round-cell infiltration around the blood vessels and mucopolysaccharides being deposited in the corium. They believed these cases represented a new entity and called it "round-cell erythematosis." Steigleder et al[2,3] reported five patients (including the three patients of Lischka and Orthenberger) in more detail later. All had a net-like, erythematous eruption on the chest and/or back with slight infiltration and mild itching. Mucous membranes, genitalia, and internal organs were not involved. Histologic examination of the involved skin showed a nonspecific round-cell infiltration around the blood vessels and diffuse deposits of substance in the dermis that stained with Alcian blue. Extensive clinical and laboratory investigations failed to show any other abnormality. They believed that these cases represent a new entity and suggested the name REM syndrome (reticular erythematous mucinosis). We report a patient with similar clinical and histologic features, but with involvement of the gums and a fluctuating nonspecific cervical lymphadenopathy.

REPORT OF A CASE

A 42-year-old woman was seen at the Dermatological Out-Patient Clinic at Hull Royal Infirmary in July 1967 with red eruptions on her chest and back, which she first noticed in April 1967. The eruptions were mildly pruritic. Cervical lymphadenopathy had been present since November 1966. Her previous health was good, and she denied receiving any drugs. There was no history of photosensitivity. On examination, she had a diamond-shaped, reticular, slightly palpable, erythematous area on her back (Fig 1 and 2) and similar but less obvious lesions on the anterior part of her chest wall. She had firm, rubbery, enlarged lymph glands on both sides of her neck and one in the left axilla. She was edentulous, and her gums appeared to be swollen and waxy (Fig 3). Apart from these findings, results of the physical examination were within normal limits.

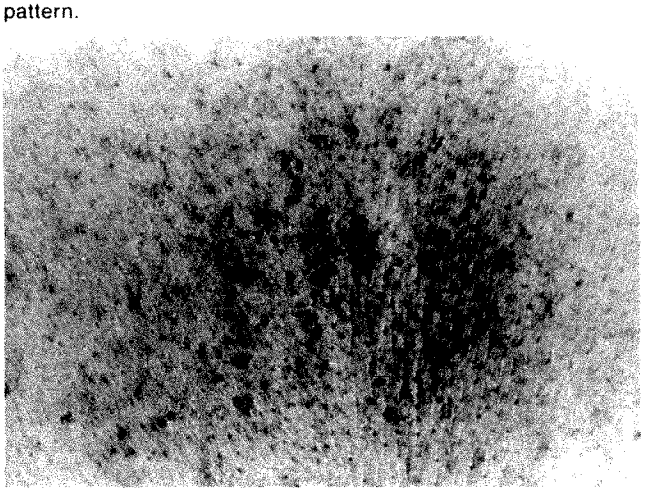
INVESTIGATIONS

Histologic studies were performed in August 1967. A skin biopsy specimen from her back showed that the epidermis was normal. The dermis looked swollen, and collagen bundles were fragmented. The skin appendages were surrounded by a moderately dense lymphocytic infiltrate. Increased amounts of hyaluronic acid were present in the dermis that stained with Alcian blue. Staining with methyl violet was negative for amyloid.

A biopsy specimen from her right upper gum showed that the epithelium was normal but that the collagen bundles were fragmented in the dermis. Staining with Alcian blue showed that hyaluronic acid was being abundantly deposited throughout the dermis. A biopsy specimen from a lymph gland from the left posterior triangle of her neck was taken. There were nonspecific inflammatory changes with prominent lymphoid

Fig 1.—Diamond-shaped, reticular, slightly palpable, erythematous area on back.

Fig 2.—Close-up view of lesions on back showing reticular pattern.



follicles, a little sinus catarrh, some hyperplasia of medullary cells, and a little fibrosis.

In November 1975 another biopsy specimen of skin was taken from her back. The epidermis showed patchy atrophy with follicular hyperkeratosis. The collagen bundles of the upper part of the dermis appeared separated, and there was a low-grade perifolliculitis with patchy lymphocytic, histiocytic infiltration and some new blood vessel formation (Fig 4). In one pilosebaceous follicle, there was an area of degeneration in the upper part of the follicle.

Histochemical Findings

On staining with Alcian blue, granular and filamentous deposits of Alcian blue-positive material were found in the spaces between the separated collagen bundles of the upper part of the dermis (Fig 5). Pretreatment of the sections with testicular hyaluronidase (strength, approximately 750 National Formulary units/mg) resulted in this material becoming unstainable with Alcian blue. The area of degeneration in the hair follicle also stained strongly with Alcian blue, confirming that this was follicular mucinosis. The material in the dermis did not stain with mucicarmine of Gomori hexamine silver, and there was no evidence of amyloid or abnormal lipids.

Immunofluorescence studies were carried out. The full range of direct immunofluorescence tests performed (polyvalent, IgA, IgG, IgM conju-

Fig 3.—Swollen, waxy-looking gums.

gates) on the skin biopsy specimen gave negative results in every case. In particular, only evidence of autofluorescence of dermal collagen was found, with no pathologic significance, as judged by control specimens processed at the same time.

Laboratory Investigations

Laboratory studies disclosed the following values: hemoglobin, 14.8 gm/100 ml; WBC count, 5.0/cu mm; film, differential WBC count, and platelet counts, within normal limits; ESR (Westergren), 4 mm/hr; blood glucose, 80 mg/100 ml (fasting); BUN, 21 mg/100 ml; serum electrolytes, normal; serum albumin, 4.3 gm/100 ml; serum globulin, 1.9 gm/100 ml; electrophoresis of serum proteins, normal; serum calcium, 9.6 mg/100 ml; serum inorganic phosphorus, 2.7 mg/100 ml; serum alkaline phosphatase, 8 King-Armstrong units/100 ml; SGOT, 4 units/ml; SGPT, 12 units/ml; serum bilirubin, 0.2 mg/100 ml; serum creatinine, 1.2 mg/100 ml; creatinine clearance, 66 ml/min; serum protein-bound iodine, 7.6 μg/100 ml. A midstream specimen of urine did not contain protein; cells, casts, and culture for bacteria were negative. Ultracentrifugal examination of patient's serum did not show abnormal proteins. Serum immunoelectrophoresis studies disclosed the following values: IgA, 50 IU/ml; IgG, 64 IU/ml; IGM, 103 IU/ml.

The chemical screening test for erythropoietic protoporphyria was negative. Fecal porphyrins: coproporphyrins, 12 μg/gm dry weight; and protoporphyrins, 19 μg/gm dry weight; urinary porphyrins: coproporphyrins, 10 μg/24 hr; and uroporphyrins, 48 μg/24 hr. Results of the antinuclear antibody test and of the Paul Bunnell screening test were negative. A culture from a throat swab showed profuse growth of *Streptococcus viridans*. Laboratory studies disclosed an anti-streptolysin O titer of 100 Todd units. Virus antibody titers were within normal limits against the following: influenza A, B, C; parainfluenza I and III; adenovirus; *Rickettsia burnetii;* psittacosis; *Mycoplasma pneumoniae;* respiratory syncytial; mumps S and V; herpes simplex; and measles viruses. A chest roentgenogram and a barium meal and follow-through showed no abnormalities. Results of a laryngoscopy also showed no abnormalities.

PROGRESS

During the past seven years, the patient remained under periodic observation. Various topical corticosteroids were administered, but none had any effect on her skin. The skin and gum lesions remained essentially the same, and mild itching periodically affected her back. Lymphadenopathy intermittently was present. During the past two years, she frequently complained of lassitude.

After Steigleder et al[3] and Montgomery and Underwood[4] reported some success using chloroquine phosphate in their cases of REM syndrome, our patient was discharged on a regimen of 200 mg of hydroxychloroquine sulfate twice daily on Nov 12, 1974. Ten days later, she developed an itching, extensive morbilliform, erythematous eruption all over her body, limbs, and face, which was suggestive of a drug reaction to the hydroxychloroquine. Treatment was stopped immediately, and the morbilliform, erythematous lesions gradually cleared in two weeks. The original lesions remained unchanged.

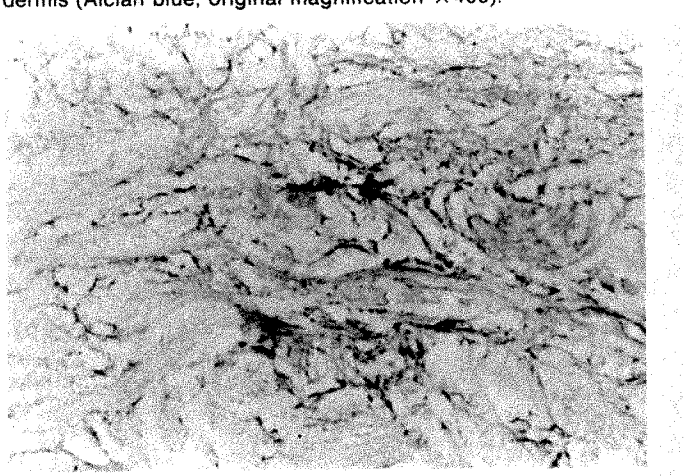
COMMENT

Cutaneous mucinosis includes those conditions in which a mucinous material, mostly acid mucopolysaccharides, accumulate in the dermis. The first condition that was recognized to belong to this group was generalized myxedema secondary to hypothyroidism. Later, pretibial myxedema, following treated hyperthyroidism, was added. Further studies showed conditions in which deposits of mucin were present in the skin over large areas in the absence of endocrinopathy, and the term lichen myxedematosus, or papular mucinosis, was applied to these.

It soon became apparent that deposits of mucin in lichen myxedematosus, or papular mucinosis, may take up different morphologic forms. In 1953, Montgomery and Underwood[4] clas-

Fig 4.—Histologic findings showing follicular hyperkeratosis separation of collagen bundles of upper dermis and patchy lymphocytic and histiocytic infiltration and some new blood vessel formation (hematoxylin-eosin, original magnification ×80).

Fig 5.—Histologic findings showing granular and filamentous deposits in spaces between separated collagen bundles of upper dermis (Alcian blue, original magnification ×400).



sified them into the following four groups: (1) generalized lichenoid papular, (2) discrete papular, (3) localized or generalized lichenoid plaques, and (4) urticarial and nodular type.

Perry et al (1960)[5] described a plaque-like form of cutaneous mucinosis in three patients who had persistent erythematous plaques on the anterior and posterior aspects of the thorax. The lesions were composed of closely net erythematous, somewhat urticarial papules that persisted for up to eight years. They were mildly pruritic, and exposure to sunshine aggravated them. Histologic sections stained with Mayer mucicarmine showed a bright-pink, heavy deposit beneath the epidermis that was patchily distributed throughout the upper part of the corium. The deposits stained with Alcian blue metachromatically and also stained with PAS. Treatment of unstained sections with hyaluronidase, prior to subsequent staining with toluidine blue, eradicated the deposits.

McCarthy et al (1964)[6] found abnormal serum globulins in a case of papular mucinosis, which have been classified as 7S immunoglobulins. These findings with the demonstrated presence of the long-acting thyroid stimulator,[7,8] also an immunoglobulin of the 7S class, in pretibial myxedema, suggest a role for immunoglobulins in the pathogenesis of altered mucopolysaccharide metabolism in the skin.

Lischka and Orthenberger (1972)[1] and Steigleder et al (1974)[2,3] described another form of mucinosis with new morphologic manifestations. Only the skin was involved, and extensive investigations failed to show underlying disease. Although their cases were similar to the case reported by Perry et al (1960),[5] clinical and histochemical differences justify their separation from existing forms of mucinosis.

Howsden et al (1975)[9] described a 70-year-old woman with a papular type of lichen myxedematosus. The authors demonstrated the presence of a yellow-green immunofluorescence between autofluorescent elastic fibers in skin biopsy specimens incubated with fluorescence-labeled goat anti-human IgG. No abnormal protein was detected in the patient's blood. Treatment with cyclophosphamide and prednisolone reduced itching after one month of treatment, when administration of prednisolone was discontinued. Three months later, the skin was less indurated, and after one year of treatment with cyclophosphamide, the skin became completely normal. Skin biopsy specimens that were taken at this time showed diminution in the number of fibroblasts and mucin.

Our case seems to represent yet another variant of mucinosis. The morphologic features and histochemical findings in our patient are similar to those described by Lischka and Orthenberger[1] and Steigleder et al.[2,3] In our patient, however, the gums were also affected, and an evanescent, nonspecific lymphadenopathy affecting the cervical and left axillary lymph glands was also present. The importance of this remains unclear. Immunofluorescence studies gave negative results in our patient. Since previous investigators did not do immunofluorescence studies in their patients, we cannot compare our findings. The skin lesions of the patients of Perry et al[5] and Steigleder et al[2,3] appeared to be aggravated by exposure to sunshine, which was not the case with our patient.

We are not certain whether our case is a true case of REM syndrome. We also wonder whether the cases of Perry et al,[5] Steigleder et al,[2,3] and of ourselves are separate entities. We would be inclined to believe that the various forms of papular, plaque-like, and reticular mucinosis are part of a whole spectrum of conditions in which mucopolysaccharides are deposited in the dermis. In some of these cases, immunoglobulins are also present in the serum and in the dermis. These findings, along with the fact that mucinous deposits are found around the blood vessels in internal organs at necropsy,[10] suggest that these conditions may constitute a generalized disorder of mucopolysaccharides.

P. Bury, MD, was consultant pathologist for the first histologic report. Professor J.A. Milne, FRCP, MRCPath, performed the second skin biopsy in November 1975 and provided the histochemical reports and photomicrographs. M. Sephton provided secretarial help.

Mucocutaneous Lymph Node Syndrome

Lt Col Richard B. Odom, MC, USA, Capt Eric G. Olson, MC, USA

• In 1967, Kawasaki reported an acute, febrile, mucocutaneous condition accompanied by swelling of cervical lymph nodes that afflicted infants and young children in Japan. He called the entity mucocutaneous lymph node syndrome. In 1974, the condition was reported in Hawaii, and several cases have been reported subsequently from the continental Unites States and other countries. One percent to two% of patients had died suddenly of cardiac failure. Rickettsia-like bodies have been demonstrated from skin and lymph node biopsy specimens, and the pathologic features suggest a relationship to infantile periarteritis nodosa.

(*Arch Dermatol* 113:339-340, 1977)

In early 1961, Kawasaki began noting a disease in infants and young children in Japan that manifested as an acute, febrile, mucocutaneous condition accompanied by swelling of cervical lymph nodes. He[1] reported 50 cases in 1967 under the title mucocutaneous lymph node syndrome (MLNS). More than 6,000 cases from Japan have been recorded through 1973.[2] In 1974, Melish et al[3] reported the cases of nine patients from Hawaii with a similar syndrome, and several cases of MLNS have been reported subsequently from the continental United States.[4-9] Cases indistinguishable from MLNS have been observed in Canada,[10,11] Greece,[12] and Korea.[13]

The MLNS can be misdiagnosed as scarlet fever, the Stevens-Johnson syndrome, infantile periarteritis nodosa, systemic juvenile rheumatoid arthritis,[14] or other acute febrile exanthems. The importance of the condition is related to the fact that a small percentage (1% to 2%) of patients affected develop sudden cardiac failure that usually results in death from myocardial infarction with coronary artery thrombosis and aneurysm.[15]

A patient with MLNS was seen in our clinic. In view of the dramatic mucocutaneous findings and major potential systemic complications associated with this condition, we wish to report this case, briefly review the literature, and alert dermatologists to enable recognition and accurate diagnosis of this new, intriguing, and possibly increasing disease in the United States.

REPORT OF A CASE

An eight-year-old boy developed fever, sore tongue, diarrhea, cough, and generalized rash three days before visiting the pediatric clinic. He had a generalized erythematous, maculopapular rash that involved predominantly the trunk and the intertriginous areas. Conjunctivitis and mild periorbital swelling were noted. The papillae of the tongue were erythematous and hypertrophic (strawberry tongue). The pharynx was normal. A mild, nonproductive cough was noted. Throat culture grew *Staphylococcus aureus*. Previous history disclosed episodes of seasonal allergic rhinitis and eczema of cheeks. Maternal history disclosed allergic rhinitis. Diphenhydramine and 1% hydrocortisone cream were prescribed.

The day following the clinic visit, the hands and feet became erythematous and edematous, and the lips were noted to be dry and fissured. Two days later, desquamation of the hands and feet were noted to begin at the base of the fingernails and toenails.

On the sixth day after the initial visit, the patient was referred to the dermatology clinic. Physical findings included a temperature of 37.6 C; large, tender, right anterior cervical lymphadenopathy; mild periorbital swelling; dryness and fissuring of the lips; hypertrophied papillae of the tongue; a fine desquamation of the trunk; and marked desquamation of the distal portion of the fingers, toes, and plantar surfaces of the feet (Fig 1 and 2). Examination four weeks later revealed transverse depressions of all fingernails and toenails (Beau lines).

Results of the following laboratory studies were normal: antistreptolysin O titers

Fig 1.—Dry, fissured exfoliation of lips and marked desquamation of distal aspect of fingers.

Fig 2.—Marked desquamation of distal aspect of fingers, toes, and plantar surfaces of feet.

and streptozyme determinations (immediately and at one month); C reactive protein; complete blood cell count; serum protein electrophoresis; serologic studies for viruses and rickettsiae; and febrile agglutinins. (All determinations were made from serum samples collected one month following the acute illness.)

Approximately three weeks after the onset of symptoms, the cutaneous, mucosal, and lymph node abnormalities had resolved. However, fatigue persisted for two more weeks. Subsequently, the patient's health has been excellent and without sequelae, except for the obvious Beau lines of all nails.

COMMENT

The principal features of MLNS are as follows: (1) fever ranging from 38.0 to 40.0 C, which lasts from one to two weeks or more and is not affected by antibiotic therapy; (2) bilateral conjunctival congestion; (3) diffuse reddening of the lips, which become dry, fissured, and eroded; diffuse erythema and prominent papillae of the tongue strikingly similar to the "strawberry tongue" of scarlet fever; diffusely erythematous oropharyngeal mucosa; (4) acute nonpurulent enlargement of the cervical lymph nodes; (5) initial erythema of the palms and soles with indurative edema (sclerodermoid) followed in the convalescent stage by a striking desquamation beginning in the junction of the nails and skin on the tips of the fingers and toes; (6) polymorphous exanthem of the torso described as generalized scarlatiniform erythroderma, maculopapular morbilliform eruption, or erythema multiforme in configuration; and (7) age of onset usually below 5 years.

Other important findings include (1) carditis, especially myocarditis and pericarditis; (2) diarrhea; (3) arthralgia or arthritis; (4) urethritis; (5) aseptic meningitis; (6) focal encephalopathy; and (7) mild jaundice.

Laboratory abnormalities include leukocytosis with shift to the left, increased ESR, proteinuria and pyuria, slight decrease in erythrocyte and hemoglobin levels, positive C reactive protein, increased α_2-globulin, thrombocytosis in second or third week of illness, mild elevations of serum transaminase level and abnormal results of cardiac studies. Rickettsia-like bodies have been found by electron microscopy inside cytoplasmic vacuoles of macrophages and inside the vascular lumen in biopsy specimens of the skin and lymph nodes from patients with MLNS.[16]

Normal studies include antistreptolysin O titers and bacterial cultures of blood, urine, stool, lymph nodes, and CSF. Viral cultures and serologic studies have been negative. *Chlamydia* antibodies, leptospiral agglutinins, febrile agglutinins, and rickettsial antibody titers have been unrevealing. Titers for antinuclear antibodies and rheumatoid factor have been negative.

Etiological speculations are as follows: (1) a hyperimmune response to any of a variety of different infections; (2) a viral syndrome; (3) an allergic or toxic response to pollutants, drugs, or unidentified toxic agents; and (4) a rickettsial disease.

The disease has failed to respond to treatment with various antibiotics, including penicillin. Steroids appear to have an antifebrile effect on the disease, but do not appear to influence the course or duration.

Pure mild Ivory is one of the safest possible soaps you can recommend for delicate skin. More doctors recommend Ivory than any other soap.

It makes sense. Ivory's absence of many extra ingredients helps minimize chances of irritation.

Thirty-eight years of laboratory testing—including patch tests and arm immersion experiments—confirm that Ivory is one of the mildest, least irritating soaps you can recommend.

And 89 years of safe consumer use support this clinical experience.

Ivory may safely be used as an adjunct to treatment of scabies, seborrhea and impetigo.

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform®-Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone
(iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

Consult complete product literature before prescribing.

Current Concepts in the Immunology of Leprosy

Thomas H. Rea, MD, Norman E. Levan, MD

This review is intended to acquaint the nonleprologist with current immunologic concepts of leprosy and with the data that support these concepts. For further reading, the reviews by Rees,[1] Wager,[2] Turk and Bryceson,[3] Bullock,[4] Skinsnes,[5] Convit and Ulrich,[6] and a memoranda sponsored by the World Health Organization[7] are recommended.

CLASSIFICATION

Rabello's polar concept of leprosy[8,9] and the studies of Ridley and co-workers,[10-12] which were based on clinical and histological observations, have been pivotal in the formation of current ideas concerning immunologic mechanisms in the pathogenesis of leprosy. Ridley and co-workers[10-12] have provided nomenclature, in the form of a system of diagnostic classification, that is fundamental to most current immunological investigations.

For those readers who are not conversant with the classification of leprosy, two analogies may be helpful. Leprosy is likened to a salami that can be taken as a whole or sliced, either thickly or thinly. When thickly sliced into two pieces, one is tuberculoid leprosy and the other is lepromatous leprosy. For most purposes such thick pieces are awkward, ie, many cases are difficult to class as either tuberculoid or lepromatous and so the salami is sliced into three less-thick pieces: tuberculoid, borderline, and lepromatous leprosy. Ridley and co-workers recognized that even thinner slices were possible histologically and clinically and were desirable when studying patients immunologically; hence their classifications as described below. In the second analogy, cells of the macrophage series are regarded as good but not very bright soldiers. In polar lepromatous leprosy, the soldier-histiocyte phagocytizes *Mycobacterium leprae* and provides a milieu for its growth. If ordered to do something against *M leprae*, it is effective. When a macrophage receives orders from an antigen-specific T-lymphocyte, like a good soldier it promptly obeys and transforms itself into a bacteriolytic epithelioid cell. To mix the metaphors, polar lepromatous leprosy is that extreme end of the salami in which the histiocyte receives no instructions from antigen-specific T-lymphocytes. Each of the other slices represents clinical and histologic constellations that originate in differing degrees of instructions provided by antigen-specific T-lymphocytes. A summary of the clinical and histological features in each of the stages of the Ridley-Jopling five-membered classification, with emphasis on those traits interpretable as reflecting the influence (or absence thereof) of specific T-lymphocytes, is found in the Table.

As an elaboration of the polar concept, Ridley and Jopling[10,11] first proposed a five-membered system of classification. They retained the traditional tuberculoid pole (TT), lepromatous pole (LL), and borderline group (BB), but added two intermediary categories: borderline with tuberculoid features (BT) and borderline with lepromatous features (BL)—TT, BT, BB, BL, and LL comprise a spectrum in continuity.

They reasoned that each stage in the spectrum was determined by and the result of host responses to antigens of *M leprae;* ie, patients with BL have more immunity against *M leprae* than do patients with LL, but less than patients with BB. To confirm this hypothesis, they measured the rate of disappearance of acid-fast bacilli (AFB)[10] in tissue specimens from sulfone-treated patients, with the assumption that sulfone therapy caused the death of organisms equally rapidly but that variation in destruction of organisms by macrophages was influenced primarily by immune responses. (This latter assumption has been partially verified by Drutz et al,[13] who found that blood monocyte-derived macrophages from leprosy patients are normal in vitro, and by Convit et al,[14] who found that nonspecifically, immunologically activated macrophages in lepromatous patients are highly bacteriolytic for *M leprae*.) The rate of disappearance of AFB was found to be significantly greater in patients with BB than in patients with BL and greater in patients with BL than in patients with LL, thus providing indirect support for their hypothesis.

In studying patients in Malaya, Ridley and Waters[12] later separated from the Ridley-Jopling LL category a sixth group that lay between true polar lepromatous and BL; this subpolar category they named leproma indefinite (LI). Patients with LI were found to clear AFB more rapidly than patients with LL.

An analogous tuberculoid indefinite (TI) group that lay between TT and

Accepted for publication Aug 25, 1976.

Clinical and Histologic Features of Ridley-Jopling Classification of Leprosy

Clinical and Histologic Features	Polar Tuberculoid (TT)	Borderline With Tuberculoid Features (BT)	Borderline (BB)	Borderline With Lepromatous Features (BL)	Polar Lepromatous (LL)
Skin lesions	Few in number; sharply defined, active border with clearing center; asymmetrical	Smaller, more numerous than lesions of TT	Annular lesions with sharply defined inner margins and ill-defined peripheral margins	Annular lesions of BB type mixed with nodular lesions of LL type	Ill-defined nodules and/or generalized diffuse infiltration; symmetrical; leonine facies and eyebrow alopecia
Nerve lesions	Skin lesions anesthesia early; nerve trunk palsies	As in TT	As in TT	Mixed TT and LL	Skin lesions, no anesthesia early; no nerve trunk palsies; symmetrical acral, distal anesthesia.
Organisms	Rare—less than 1 per 100 oil-emersion fields	Rare to 1 per 10 oil-emersion fields, More in nerve bundles	1 to 10 per oil-emersion field	10 to 100 per oil-emersion field	10 to 1,000 per oil-emersion field
Monocytic Derivatives					
Histiocytes	Absent	Absent	Absent	Present without foamy change	Present with foamy change
Epithelioid cells	Present	Present	Present	Present	Absent
Langerhan giant cells	Present	Present	Absent	Absent	Absent
Lymphocytes	Present; dense peripheral infiltration about granuloma; infiltration into epidermis	Present; peripheral infiltration about granuloma, no epidermal infiltration	Variable; diffuse and focal (nerve) distribution	Scant; focal areas of infiltration, especially perineural cuffs	Scant; diffuse in distribution
Lepromin skin test	Usually positive	Variable	Negative	Negative	Negative

BT was defined,[15] which completed a seven-membered spectrum—TT, TI, BT, BB, BL, LI, and LL in continuity. In actual practice, some investigators use the five-membered system and others use the seven. Unless otherwise specified, the Ridley system refers to the seven-membered system in the rest of this review.

The Ridley system is useful primarily because it is the most precise method of establishing patient comparability among the diverse ethnic and geographic groups that are studied. The Ridley system has proved to be clinically useful also: TT and LL patients are stable, whereas TI through LI patients are apt to spontaneously change clinical or histologic features; clinical lesions of tuberculoid and borderline type and nerve trunk palsies are signs of cell-mediated immunity against antigens of *M leprae*.

The Ridley system is not without its difficulties. A troublesome problem is the immunologic validity of the distinction between LI and LL, ie, do LI patients have more cell-mediated immunity against *M leprae* than do LL patients? (Has the salami been sliced too thinly to be meaningful?)

In a study of the rates of disappearance of bacilli with treatment, Russell et al[16] grouped together responses of LL patients and a subpolar group designated by them as BL/LL, which presumably is similar to LI. It is reasonable to infer that they found no meaningful difference in the rate of disappearance of organisms between polar and subpolar patients, thus lending no support to an LL-LI distinction as judged by this criterion. Myrvang et al[17] studied *M leprae*-induced lymphocyte transformation and migration-inhibition factor production and found that lymphocytes from patients with LI did not respond in a greatly different manner than those from patients with LL, which suggests that the distinction between LL and LI may be spurious immunologically. We have found that many of our Mexican patients are histologically classifiable as LI but have clinical features of LL. Thus, we believe that the histologic distinction between LL and LI is without importance, at least as applied to these particular patients.[18,19]

Superimposable on various segments of the granulomatous spectrum of leprosy are a variety of reactional states, including at least three types.

Erythema nodosum leprosum (ENL)[18] is characterized clinically by crops of tender skin and subcutaneous nodules that typically arise in grossly uninvolved tissue. Histologically ENL is characterized by a neutrophilic and lymphocytic inflammatory infiltrate that is superimposed on the previously subclinical lepromatous granuloma. Erythema nodosum leprosum is often seen after the onset of chemotherapy, but its occurrence in the absence of chemotherapy is not unusual. Erythema nodosum leprosum is most common in LL patients, but is seen with progressively less frequency in patients with LI and BL.[11,12]

The Lucio phenomenon,[20] which is observed most commonly but not exclusively in patients from Mexico, is characterized clinically by crops of irregular, stellate infarctions of the skin in individuals with pure diffuse leprosy, ie, without nodular lesions and with alopecia of the eyebrows. The Lucio phenomenon is characterized histologically by severe vasculitis of the dermal vessels. Systematic study of the Lucio phenomenon according to the Ridley system has not been made, but in our experience these patients are clinically classifiable as LL.[19] Usually the Lucio phenomenon is observed prior to chemotherapy.

A third (or perhaps a third and fourth) type of reaction has no entirely satisfactory or universally accepted terminology. Ridley[21] has proposed the terms "downgrading" and "reversal reactions," which obligatorily imply a decreasing or increasing amount of immunity directed against *M leprae;* reversal reaction will be used in this review (synonyms, acute phase and reactional tuberculoid state).

These reactions are characterized clinically by an increase in tissue reaction in skin lesions already grossly evident and the abrupt onset of nerve trunk palsies, and histologically by the granuloma of leprosy with edema but without vasculitis or acute inflammatory infiltrate. This type of reaction does not occur in patients with LL (except after the use of transfer factor),[22,23] but is seen throughout the rest of the leprosy spectrum, either in the presence or in the absence of chemotherapy.

LEPROMIN REACTIVITY

Lepromin,[1] the skin-test antigen widely used in studies of leprosy, has no diagnostic value. The antigen, which is derived from autoclaved lepromatous tissue, contains dead *M leprae*. Because lepromin is particulate, devoid of heat-labile determinants, contaminated with host-tissue antigens, and scarce, it is less than ideal.

Three types of positive responses to intradermal lepromin have been described. A delayed 21-day (or longer) response with histologic characteristics of a tuberculoid granuloma, the Mitsuda reaction,[1] is particularly well elicited by the Mitsuda or integral type of lepromin; it has not been reproducibly passively transferred with whole lymphocytes[24,25] or transfer factor.[22,26] A delayed 48-hour response with the histologic characteristics of a tuberculin reaction, the Fernandez reaction,[1] is particularly well elicited by the Dharmendra type of lepromin and has been irregularly conferred on LL patients with previously negative reactions with whole lymphocytes[24,25] or transfer factor.[22,23,26] An immediate reaction, the Medina reaction, has been inconsistently observed in patients with the Lucio phenomenon and is of no further importance in this review.[20,27] For clarity, "lepromin responsivity" will subsequently refer to both Mitsuda and Fernandez responsivity.

Patients with TT and TI are lepromin-positive; BB through LL patients are lepromin-negative; and BT patients are either lepromin-negative or lepromin-positive. Thus, lepromin responsivity is of some prognostic value.[11] In BB through LL patients, lepromin unresponsiveness is not invariable: Guinto[28] reports no Fernandez responsiveness at 10 mm or more of induration and a 1% rate of Mitsuda responsiveness at the 5 mm or more of induration; Mukerjee and Kundu[29] found Mitsuda reactivity in one of 15 "frank lepromatous" patients; Leiker[30] found no Mitsuda reactivity at 3 mm or more induration in 54 patients with diffuse lepromatous leprosy, but weak Mitsuda reactivity at 3 to 5 mm of induration was present in seven of 53 (13%) "nondiffuse" lepromatous patients; Talwar et al[31] reported Fernandez responsiveness in one of two patients who were histologically classed as LL; Convit et al[32] reported Fernandez reactivity at 10 mm or more of induration in 4% to 8% of lepromatous patients and Mitsuda reactivity at 3 mm or more of induration in 10% to 34%, with the least involved showing the greatest reactivity. These positive reactions are usually weak and may represent responses to host-tissue elements contaminating the lepromin(s) used. Uncertainty may be anticipated until a pure antigen is available. Conversely, in TT through TI patients, lepromin responsiveness is not invariable; Guinto[28] reported Fernandez responsiveness in 39% and Mitsuda responsiveness in 94% of tuberculoid patients.

Lepromin responsiveness, especially of the Mitsuda type, is the rule in normal adults,[1] which makes lepromin responsivity of no diagnostic value. In a large population in an endemic area, Guinto et al[33] found that the rate of Mitsuda responsiveness increased with age. Mitsuda reactivity was found in 17% of those 4 years old or less, but was found in 95% of those 20 years old or more. Also, these investigators found that the rates of Mitsuda responsivity were similar in individuals from households with lepromatous leprosy, with nonlepromatous leprosy, or without leprosy.[34] In normal adult individuals with leprosarium exposure, Convit et al[32] found a 37% rate of Fernandez responsivity (10 mm) and a 96% rate of Mitsuda responsivity (3 mm). In a nonendemic area (New York), Rotberg et al[35] reported a 19% rate of Fernandez responsivity and an 86% rate of Mitsuda responsivity among 64 healthy controls. Similarly, in a study of 73 adults not exposed to leprosy, Shepard and Saitz[36] found a 22% rate of Fernandez responsivity (10 mm) and a 100% rate of Mitsuda responsivity (3 mm). Waters[37] found a 2% rate of Fernandez responsivity (10 mm) and 43% rate of Mitsuda responsivity (5 mm) in 65 tuberculin-negative residents of England who had not been exposed to leprosy.

There is no definite answer to the question of whether lepromin responsivity arises from cross-reactivity with tuberculin sensitivity. Rotberg et al[35] argued that it probably does and cite cross-reactivity (but do not prove its existence) to explain Fernandez reactions in New Yorkers; Waters' data support this view.[37] Shepard and Saitz[36] reasoned with substantial evidence that cross-reactivity with tuberculin does not explain the Fernandez reactivity they observed. Doull et al[38,39] and Guinto et al[40] concluded that Mitsuda responsiveness cannot be explained by prior exposure to either *M leprae* or other mycobacteria.

Does BCG vaccination influence lepromin responsiveness? In patients with lepromatous leprosy, BCG vaccination will produce a transient Mitsuda responsiveness in one half of the individuals so treated, but this neither alters Fernandez nonresponsiveness nor alters the patient's clinical condition.[41] In patients with tuberculoid disease, BCG vaccination does not increase lepromin responsiveness.[41] In tuberculin-negative normal children, BCG vaccination will accelerate conversion to lepromin positivity, as does lepromin testing.[38]

The mechanism of lepromin responsiveness is not known. Some observations support the hypothesis that lepromin responsivity is a cell-mediated immune reaction: (1) Fernandez reactivity can be transferred passively with the use of whole lymphocytes[24] or transfer factor;[22] (2) the histologic characteristics of the Fernandez reaction are similar to those of a tuberculin reaction[1]; (3) the high rate of Mitsuda responsivity in tuberculin-negative individuals who have not been exposed to leprosy can be explained by the eliciting dose becoming the sensitizing dose[1]; and (4) (weakest of these arguments) Fernandez reactivity in patients who have not been exposed to leprosy is a matter of cross-reactivity.[35]

Other observations support the hypothesis that lepromin responsivity is not cell-mediated immunity, but is a

phenomena of unknown mechanism: (1) Mitsuda reactivity has not been convincingly passively transferred[22,24-26]; (2) cross-reactivity is not an adequate explanation for Fernandez responsivity in unexposed, tuberculin-negative individuals[36]; (3) the rate of conversion to Mitsuda positivity is greater than that of conversion to tuberculin positivity and cannot be explained by exposure to leprosy[38-40] and is difficult to explain by lepromin testing[38]; (4) results of lepromin-induced lymphocyte transformation studies are usually negative in unexposed adults,[42] but such individuals are usually Mitsuda-positive.

That the mechanism of lepromin unresponsiveness is unknown is evident. In infants, "immaturity" is an easy explanation, but begs the basic question. In adults with LL to BB disease, it is uncertain whether disease develops because of unresponsiveness or if unresponsiveness is a consequence of disease development. Dharmendra and Chattergee's[43] follow-up of lepromin-negative individuals in an endemic area with a high incidence of lepromatous leprosy in previously lepromin-negative subjects suggests that lepromin negativity and susceptibility to lepromatous leprosy may be closely related phenomena (or that the initial study identified patients in the incubation period of the disease.)

An understanding of lepromin unresponsiveness, the most widely reported abnormality characterizing BB to LL patients, may be central to an understanding of the pathogenesis of lepromatous disease.

CELL-MEDIATED IMMUNITY AGAINST *M LEPRAE*

Current concepts of the role of cell-mediated immunity in the pathogenesis of leprosy have their origin in the polar concept of leprosy[8] and their recent elaboration in the clinical and histologic studies of Ridley and coworkers.[10-12] Cell-mediated immunity against antigens of *M leprae* is believed to determine the following: (1) resistance or susceptibility to infection; (2) the clinical expression of the disease when infection occurs, ie, the niche occupied by the patient on the Ridley scale TT to LL is determined by the degree of cell-mediated immunity toward antigens of *M leprae;* and (3) reversal type of reactions.

From the Armauer Hansen Research Institute, Ethiopia, direct evidence in support of these ideas has been found with the use of the technique of lepromin (antigen)-induced lymphocyte transformation. Godal and Negassi[42] studied lymphocyte responses of previously exposed or unexposed health care personnel; the finding of unresponsiveness in unexposed individuals and a response rate of up to 80% in those with over one year of exposure support the concept of a common subclinical infection with control and subsequent protection being mediated by cell-mediated immunity. Myrvang et al[17] studied lymphocyte responses of patients throughout the Ridley scale, TT to LL; they found progressively decreasing responsivity as one "descended" from TT toward LL and virtually no responsivity at all among LI and LL patients. This finding supports the concept that a patient's Ridley classification (particularly using the five-membered system) is quantitatively related to the degree of cell-mediated immunity directed against antigens of *M leprae*. Godal et al,[44] Samuel et al,[45] and Barnetson et al[46] studied lymphocyte response of patients before, during, and after reactions of the reversal type; they found a definite increase in lymphocyte responsivity to lepromin during the reaction and a decrease during the postreaction phase. The administration of transfer factor to lepromatous (LL) patients is associated with the development of a "reversal" reaction,[22,23] which is further, albeit indirect evidence that such reactions are mediated by cell-mediated immunity.

CELL-MEDIATED IMMUNITY AGAINST ANTIGENS OTHER THAN *M LEPRAE*

Generalized impairment of cell-mediated immune responses, ie, responses to antigens other than those of *M leprae*, has been reported in lepromatous patients (BL to LL) in diverse ethnic groups and from several geographic areas. Methods of study have included intradermal skin tests,[19,28,31,32,47-56] epicutaneous allergic sensitization to a haptene,[19,32,50-53,55-57] allograft rejection,[58] antigen-[17,59-62] or mitogen-induced[19,31,34,39,60,62-69] lymphocyte transformation, and measurement of peripheral[19,70-73] blood T-lymphocytes and lymphokine production in vitro.[31,52]

This generalized impairment of cell-mediated immunity is a phenomenon separable from that of lepromin unresponsiveness. Within populations with a generalized impairment of cell-mediated immunity are some individuals who show no evidence of this impairment[32,57]; some entire populations display no generalized impairment but are, as expected, unresponsive to lepromin.[19,32,68] When the generalized impairment is present, it may diminish with antileprosy chemotherapy,[51,67] but lepromin unresponsiveness persists.[1,29]

The generalized impairment of cell-mediated immunity thus does not appear to be the cause of lepromin unresponsiveness, a predisposing cause of leprosy, or a necessary sequellae of leprosy.

The mechanisms of the generalized impairment of cell-mediated immunity are unknown. In other infectious diseases, an antigen-excess state may be responsible for the development of anergy[74]; in leprosy no direct evidence bears on this point, but it is suggested indirectly by young age and evidently early state of the disease in populations without a generalized impairment of cell-mediated immunity.[19,32,68] Abnormalities in the circulation or percolation patterns of T-lymphocytes has been proposed: Turk and Waters[55,57] noted replacement of paracortical area of lymph nodes by granuloma and suggested that inability to respond normally to dinitrochlorobenzene might be secondary to this. Bullock et al[75] demonstrated changes in splenic lymphocyte populations during *M lepraemurium* infections in mice. Rook[76] demonstrated peripheral decrease in and splenic sequestration of phytohemagglutinin (PHA)-responsive lymphocytes in mice with experimentally produced *M ulcerans* infection. Nelson et al[65] found PHA responsiveness to segregate according to racial groups and suggested that genetic factors may be involved. Clinically inapparent, but histologically evident, diffuse lepromatous infiltration of the skin conceivably could influence epicutaneous haptene sensitization.[77] Other conceivably relevant

mechanisms that have not been studied include nutritional status and the presence of coincidental infections, particularly malaria and intestinal parasitosis.

At present, whether the observed generalized impairment of cell-mediated immunity adversely affects the health of lepromatous patients is open to question. Observations of associated illnesses are difficult to interpret and may be attributable to variables other than leprosy, eg, the high incidence of tuberculosis among some lepromatous groups[78] is apt to be related to a local factor, since Fernandez, in his study of Argentinians, concluded that leprosy and tuberculosis were mutually exclusive diseases.[47] Some reports do suggest that an additional burden does exist in lepromatous patients, including a high incidence of adverse vaccinia reactions,[79] a high incidence of basal cell carcinomas,[80] and a high incidence of lymphoma.[81] These reports are isolated, and other studies where evidence has been sought for a specific vulnerability that arises as a result of impaired cell-mediated immunity, such as immunosurveillance against cancer, no abnormality has been found.[82]

General cell-mediated immune responsivity has not been as extensively studied in tuberculoid patients. In some investigations a generalized impairment has been found, but of less severity than in lepromatous patients.[31,53,63,65,66] In others no generalized impairment has been identified.[31,47,52,62,67]

ANTIBODY-MEDIATED IMMUNITY

Quantitative determinations of serum immunoglobulin levels have demonstrated that lepromatous patients are apt to be hypergammaglobulinemic.[83,84] Quantitative studies of classes of immunoglobulin have shown divergent results, which may be attributable to reactional states, genetic factors, associated diseases, treatment, and disease extent. In lepromatous patients, serum IgG, IgA, and IgM levels have been variously and variably elevated. Lim and Fusaro[85] found substantial elevations of serum IgG and IgM levels; Bonomo and Dammacco,[86] Bullock et al,[87] and Sagher et al[88] found elevations of serum IgG, IgA, and IgM levels; Sheagren et al[89] found elevations of serum IgG and IgA levels; Saha and Mittal[89] found elevations of serum IgM and IgA levels; Malaviya et al[90] found an elevation of serum IgA level only ($P < .02$). The serum IgE level may be normal or even diminished, but is still not thoroughly studied.[91,92] Lim and Fusaro[85] found a significant elevation of IgA in tuberculoid patients, but this finding has not been confirmed by others. Peripheral blood B-lymphocyte levels have been found to be elevated,[70,73,93] normal,[19] or decreased[72] in lepromatous patients.

Lepromatous patients as a group may respond to a specific immunogen with substantially higher antibody titers than do controls: Buck and Hasenclever[19] found higher serum agglutination titers to *Candida albicans* in lepromatous patients than in tuberculoid patients or normals. De Almeida et al[94] found that in response to typhoid vaccination, 60 lepromatous patients produced higher titers of agglutinins to H antigen than did 60 military recruits.

Antimycobacterial antibodies, precipitins,[95-98] agglutinins,[99] and immunofluorescins,[100] are found in the sera of lepromatous patients. These antibodies react with antigens from various mycobacterial species. The lack of a pure antigen makes it impossible to know with certainty if any of the demonstrable antibodies are specific for antigens of *M leprae*. Claims of specificity usually rest on one or more assumptions; for example, (1) the complete removal of antibodies against all but *M leprae*-specific determinants occurs with absorption by material from other mycobacteria; (2) host-tissue antigens that obligatorily contaminate preparations of *M leprae* have no influence on the demonstrated antigen-antibody reactions; (3) antibodies cross-reacting with *M lepraemurium* are induced by specific *M leprae* antigens.

Immune complexes are demonstrable in the sera of lepromatous patients. Cryoglobulins were found[95,101] and proved to be of the mixed type[102,103]; these may have rheumatoid factor activity[102,103] and may contain IgA, Clq, C3, and C4, as well as IgG and IgM.[103] Further serologic evidence for the existence circulating immune complexes includes the presence of a Clq precipitin,[104-106] of a platelet agglutinin,[107] and of a factor that gives a positive Raji cell test.[103]

Less well established is the function of immune complexes in the pathogenesis of clinical phenomena. Wemambu et al[108] and Waters and associates[109] found IgG, IgM, and C3 in the vessel walls of ENL lesions; Fields and Abel[110] and Londono et al[111] found C3 but no immunoglobulin. Quismorio et al[103] found IgG, IgM, and C3 in vessel walls of Lucio phenomenon lesions. In patients with ENL, Drutz and Gutman[112] found a high incidence of glomerulonephritis, which is consistent with immune complex injury.

The questions raised by the existence of immune complexes extend beyond their possible role in the pathogenesis of ENL and Lucio phenomenon. What is the antigen in the Clq precipitable complex? What is the antigenic specificity of the IgG in the cryoglobulin? Could immune complexes have a role in the pathogenesis of LL?

A wide variety of circulating autoantibodies have been described in BL to LL patients[86,89,90,101,102,113-118]; these include antinuclear, antithyroid, and antisperm antibodies and rheumatoid factor. Studies vary in prevalence rates and in specificities found; in our own series, patients did not differ from controls.[19] The differences observed might be attributable to genetic factors, duration of disease, and methods used, but the mechanism of autoantibody production and importance remains obscure. Suggested mechanisms include defective suppressor T cells[96] and cross-reactivity with *M leprae*.[118]

A narrower range of tissue-fixed putative autoantibodies has been reported.[110,119,120] A "band" of IgM at the basement membrane of the epidermis has been observed in one third of LI to LL patients. Complement is not fixed, and the presence of the band is independent of gross involvement of the site with leprosy or the duration of treatment. Similar IgM deposits have been observed on the collagen fibrils of the papillary dermis by Quismorio et al.[120] These antibodies are of unknown importance. Perhaps they cross-react with *M leprae* or are secondary to lepromatous infiltration, but probably are unrelated to identifiable circulating autoantibodies.

Syphilitic reagin directed against cardiolipin antigen is found in the sera of about one third of BL to LL patients and is established as "false-positive" by testing for specific antitreponemal antibodies.[101] Matthews and Trautman[101] found cardiolipin reactivity in the sera disappeared with cryoprotein extraction. Bonomo and Dammacco[86] found cardiolipin reactivity restricted to the 19S fraction in some patients. Abe[121] demonstrated in a phospholipid similar to cardiolipin-lecithin in a lepromatous nodule, which suggests that antibody directed against *M leprae* may be producing the reaction.

IMMUNOTHERAPY

The most ambitious attempt to achieve some control of leprosy by immunologic means has been the use of BCG vaccination. The initial controlled study from Uganda indicated that a reduction in the incidence tuberculoid leprosy in children occurred as a result of BCG vaccination.[122] An ongoing controlled study by WHO is currently in progress in Burma; to date the incidence of leprosy is similar in vaccinated individuals and in controls.[123]

Several exploratory studies of transfer factor[22,23,26] or lymphocyte transfer[24,25,56] therapy have been reported in the treatment of LL patients. All studies have been short-term, but the results have been encouraging. Fernandez reactivity has been irregularly and transiently conferred.[22,25] (Mendes et al[56] reported transfer of Mitsuda reactivity; because the histologic characteristics of these reactions were only briefly described and because the finding has evidently not been reproduced, it is best to regard Mitsuda reactivity as nontransferrable pending further study.) Bacilli have disappeared from tissue at a more rapid rate than seen with chemotherapy.[23] Reversal reactions easily controlled by prednisone have occurred.[22,23] Long-term trials are in progress.

Lim et al[124] reported improvement in lepromatous patients associated with the administration of deliberately mismatched leukocytes. To our knowledge, confirmatory studies have not been reported.

Meyers et al[125] found that levamisole did not alter either Mitsuda or Fernandez reactivity in patients with either positive or negative responses. Nelson et al[126] found that levamisole augmented responsivity to *C albicans* antigen and dinitrofluorobenzene, but not responsivity to tuberculin in borderline and lepromatous patients.

In LL patients, BCG vaccination locally results in bacteriolysis of *M leprae*, which presumably represents a nonspecific effect of activation of macrophages by a specific, immunologic mechanism.[14] At present there is no evidence that nonspecific activation is of any potential therapeutic importance.

PERSPECTIVES

Several points of view have been constructed to explain the pathogenesis of LL.

Polar lepromatous leprosy can be viewed as an example of specific immunologic unresponsiveness (tolerance) toward antigens of *M leprae*.[61] Several models of such specific unresponsiveness are known to exist in animals. Clonal deletion,[127] which is a mechanism of unresponsiveness toward self-antigens, is attractive because it is consistent with the large amounts of *M leprae* that do accumulate. Specific inhibition by antibody or immune complexes[128] is consistent with available data, particularly the high incidence of immune complexes. Specific inhibition by "suppressor" T cells[129,130] is conceivable, but lacks supporting or negating evidence.

Rotberg has postulated a "natural" or N-factor to explain the pathogenesis of LL, and his argument was sympathetically summarized by Newell.[131] Briefly, responsiveness to lepromin and resistance to LL is conferred by an N-factor that is absent at birth but appears with maturation (as walking). The N-factor has three virtues: (1) it is consistent with lepromin reactivity in the absence of exposure or tuberculin reactivity; (2) it is consistent with Dharmendra's epidemiologic findings; (3) it is consistent with the seemingly paradoxical, always low incidence of LL but extremely variable incidence of TT through BB.

The N-factor hypothesis can be partially restated immunologically as the failure or dysfunction of an immune-response gene. The immune-response gene hypothesis[132] holds that immune responses or the lack thereof are under direct genetic control at a hypothetical immune-response locus, close to the HL-A second or B locus and the mixed leukocyte-culture locus. However, seven studies of HL-A antigens have demonstrated no consistent relationship between leprosy and HL-A antigen distribution, and thus provide no support for the immune-response gene hypothesis.[133-139]

Susceptibility to leprosy has been implicitly attributed to immunologic inexperience and is part of the rationale for the use of BCG vaccination, ie, the BCG experience will increase host resistance.

Lim et al[71] postulated that susceptibility to LL can be explained by transient immunoincompetence of the host at the time of initial exposure. Godal et al[42] argued that the predisposition to LL seen in LL families might result from tolerogenic exposure to *M leprae*, ie, prolonged ingestion of organisms. To argue by analogy with experimentally produced leishmaniasis[140] where access to lymphatic vessels by inoculum may be critical in determining whether cure or dissemination results, the potential importance of transient local factors in the pathogenesis of leprosy must be considered.

The immunologic unresponsiveness towards antigens of *M leprae* has been speculatively attributed to metabolic factors unrelated to host immunologic incompetence[5,51]; in such a scheme, an enzymatic failure in a macrophage leads to failure to form immunogen or the formation of a tolerogen. There is no evidence either for or against this idea.

Gamma Benzene Hexachloride Toxicity

A Review

Lawrence M. Solomon, MD; Lester Fahrner; Dennis P. West, MS

Scabies has once again become a major health problem. Currently, the most frequently used antiscabetic substance is a lotion containing 1% of the pesticide, gamma benzene hexachloride (lindane). Because of its widespread use in humans and because of some anecdotal communications suggesting that toxic reactions may have been observed in children treated for scabies with gamma benzene hexachloride, we felt it would be of interest to review toxicity of the substance and examine the indications and methods currently recommended for its use.

Gamma benzene hexachloride is the γ isomer of 1,2,3,4,5,6-hexachlorocyclohexane (HCCH). It is the chlorine analogue of muco-inositol.[1] It is a nonaromatic compound whose physical properties are given in the Figure.

Gamma benzene hexachloride is present in several products sold under a number of trade names. Although gamma benzene hexachloride was probably first synthesized by Michael Faraday in 1825, the pure alpha, beta, gamma, and delta isomers were not prepared until 1943 by J. C. Smart. Since that time, three other isomers have been found. The use of hexachlorocyclohexane as an insecticide was first investigated in 1942. The gamma isomer alone proved to be an effective insecticide, useful against a wide spectrum of insects and mites.[2] Since then, gamma benzene hexachloride has found numerous public health and agricultural applications.[3,4]

TOXICITY STUDIES

The acute toxicity of gamma benzene hexachloride administered by various routes has been determined in a number of warm-blooded species. The oral lethal dose for 50% survival of a group (LD_{50}) for mouse, rat, guinea pig, rabbit, dog, and sparrow ranged from 60 to 230 mg/kg of body weight. Gamma benzene hexachloride administered via subcutaneous injection in rat, guinea pig, and rabbit had an LD_{50} of from 50 to 100 mg/kg of body weight. Intraperitoneal injection resulted in an LD_{50} of 35 to 85 mg/kg of body weight in the rat, and intravenous injection had an LD_{100} of 6 mg/kg of body weight in rabbits. The LD_{50} values from cutaneous applications in the mouse, rat, guinea pig, and rabbit range from 300 to 500 mg/kg of body weight.[5] In rabbits, LD_{50} dropped from 4,000 mg/kg of body weight when gamma benzene hexachloride was applied in dry form to 50 mg/kg body weight when it was applied in an unspecified solvent,[6] indicating that the vehicle plays an important role in percutaneous penetration. Lipid vehicles increase absorption. Gamma benzene hexachloride is considered moderately toxic when compared to other insecticides. Death results often from neurotoxic effects and usually follows muscle spasms and epileptiform convulsions.[3,7,8] Necropsy of animals and humans partially poisoned by it demonstrates fatty infiltration and enlargement of the liver, pulmonary edema, numerous small brain hemorrhages, and necrosis of the wall of the small vessels.[3]

The varied responses of experimental animals subjected to gamma benzene hexachloride toxicity have been compiled in Tables 1 and 2.

The physiologic impact of exposure to gamma benzene hexachloride is in part a function of the route of administration, the dosage,[11] and the health and nutrition[42] of the animal[22] to whom it is administered. Since it is a chlorinated hydrocarbon, it is processed by the liver, primarily stored in depot fat and secondarily in other lipophilic tissues.[17,18] It is cleared from the body more readily than many other chlorinated insecticides,[17] and male rats clear the compound faster than females,[43] which may offer a

Accepted for publication Sept 13, 1976.

Chemical properties of gamma benzene hexachloride. Molecular weight, 290.84 white crystalline powder. Melting point, 112.5 C H_2O in solution (nonpolar solvent solution).

partial explanation of the greater susceptibility of the latter to toxicity.[35] In brain tissue, there is a clear preference for gamma benzene hexachloride storage in the white matter to the extent that is has been used as an experimental convulsant.[29]

Young animals appear to be particularly susceptible to gamma benzene hexachloride toxicity[44] and appear to store the substance more readily and for a longer time in the adipose tissue. Differences in animal sensitivity to gamma benzene hexachloride may be due to differences in rates of absorption, excretion rate, liver cell function, differential fatty distribution, and undefined species and individual response factors.

USES OF GAMMA BENZENE HEXACHLORIDE IN VETERINARY MEDICINE

Gamma benzene hexachloride is used as a spray, dip, or dust in veterinary medicine against ectoparasites and as a general insecticide. Its use is contraindicated in emaciated, very young, or lactating animals.[45] It has been applied against mange, lice, ticks, and fleas, as a dusting powder (0.5% to 1%), which is thoroughly brushed off after ten minutes as a spray, and most commonly as a dip in concentrations of .02% to .06%. Considerable mortality of cattle has been reported from accidental ingestion[46] or improper dipping of the animals.[21,23,47,48] As a result, precautions are clearly printed on the labels of the pharmaceuticals destined for veterinary use.

Table 1.—Disposition of Gamma Benzene Hexachloride in Experimental Animals

Route of Entry	Absorption	Local Effects	Storage
Respiratory system	Yes	Tracheitis; chemical pneumonitis	Unknown
GI tract	Absorption varies with vehicle,[10,11] simultaneous use of chlorophenols,[12,20] exercise[12-18]	Possibly gastritis and enteritis	Found in fat, kidney, brain, blood, liver, adrenals, muscle, spleen, and milk of lactating animals
Skin	Varies with particle size, exposure period, vehicle,[40] hair length of animal's coat[8,19,21,25,39]	Dermatitis; hyperkeratosis, abscess formation	Subcutaneous fat[22]

Table 2.—Toxic Effects of Gamma Benzene Hexachloride in Experimental Animals

Tissue	Toxic Symptoms	Reference Nos.
Bone marrow	Depression of hematopoiesis	24
	Porphyria*	25
Peripheral nervous system	Degeneration of neurons	26
	Sympathetic ganglionic blocking agent	27
	Lower excitability of retina	28
CNS	Seizures	7, 8
	Concentration in white matter	29, 30
	Raises threshold to seizures induced by other agents	31, 32
	Learning impairment	33
Genitals	Testicular atrophy and hypertrophy	34
Kidneys	Fatty degeneration, necrosis and compromise of function. Fat deposits in proximal convoluted tubule	7, 35, 36
Liver	Benign hepatomas	3, 37, 38
	Fatty degeneration of liver with compromise of function	5, 21, 24, 26, 35, 36, 40
Immune system	Decreased IgG response to antigen	41

*Not to be confused with hexachlorobenzene-induced porphyria.

HUMAN USE

In 1948, Wooldridge[49] successfully treated human scabies with 1% gamma benzene hexachloride cream. With recrudescence of scabetic dermatitis in recent years, this treatment is now widely used and appears to be effective.[49-52] Gamma benzene hexachloride has also been effectively used topically against pediculosis.[50,53] Although the treatment remains effective, there may be an increasing number of treatment failures.[52]

When gamma benzene hexachloride was given orally as an emulsion against oxyuriasis,[54] four of the 15 subjects treated experienced toxic symptoms, and the treatment was not considered acceptable. The reported symptoms of human gamma benzene hexachloride toxicity are as follows: nausea, vomiting, convulsions, respiratory failure with cyanosis, and sometimes death.[54-57] Recommended treatment for acute poisoning includes saline gastric lavage, emesis, oxygen therapy, calcium thiosulfate (or gluconate) injections, and phenobarbital.[9,48,53,55,57-59] Necropsy studies on patients who have had fatal reactions to gamma benzene hexachloride have detected fatty infiltration of the liver, degeneration of cardiac muscle, and necrosis of the vessels of the lungs, kidneys, and brain.

Chronic gamma benzene hexachloride exposure may occur by absorption through the skin or lungs, or gastrointestinal tract and may cause blood dyscrasias and hematopoietic depression.[9,59-72] Some of the observed effects of the hematologic system may have occurred by an immunologic mechanism,[73] since gamma benzene hexachloride was found to block the blas-

togenic effect of phytohemagglutinin on cultured human lymphocytes.[74] It was postulated that the block may result from inhibition of phosphatidylinositol formation. Inhibition of phosphatidylinositol formation by gamma benzene hexachloride was also seen in some neural preparations of experimental animals.[8,27,75] The structural similarilty of muco-inositol to phosphatidylinositol may play a central role in understanding gamma benzene hexachloride toxicity.

In a study of workers chronically exposed to gamma benzene hexachloride, a correlation was made[76] between amounts of exposure (via air and skin contact) and gamma benzene hexachloride levels in the blood. The length of exposure did not correlate positively with the blood level, and tissue levels were not studied. Examination of the formed elements of the blood in the subjects studied was not consistent with the notion of simple toxic suppression of hematopoiesis, although idiosyncratic disease responses or rare hypersensitivity could not be ruled out.[76-78] A study of pesticide worker in Hungary[79] demonstrated strong correlation between blood gamma benzene hexachloride levels above 0.02 ppm and EEG abnormalities in 15 of 17 subjects. Chronic exposure to gamma benzene in humans has also resulted in depressed liver function,[80,81] altered menses,[82] and cardiac arrhythmias.[83]

The first suggestion that major toxicity and death could be caused by exposure of the skin to gamma benzene hexachloride was reported in 1953.[58] Seventy-nine persons were affected by a 40% mixture of gamma benzene hexachloride isomers applied to the household environment, including bed covers, clothes, as well as the subjects' body surfaces. Initial symptoms were lassitude, headache, vertigo, and myalgia, followed by intestinal colic, diarrhea, and stomatitis. Finally, CNS symptoms were seen: mental confusion, blindness, dysarthria, and convulsions. One patient died following degeneration of the liver and kidneys.

In another incident a farmer had the following progression of symptoms after contact with gamma benzene hexachloride and chlorophenothane (DDT): burning and peeling of the skin, nausea, submandibularis gland abscess, mental slowness, extrasystoles, panmyelophthisis, and death. All parenchymal organs studied had been infiltrated with fat.[71]

After applying gamma benzene hexachloride in acetone to intact human skin (forearm) at least 9.3% of the substance was found by Feldmann and Maibach[84] to be absorbed and excreted in the urine during the following five days. The scrotal skin posed virtually no barrier to penetration of gamma benzene hexachloride and other pesticides.[85] Wolfe believed cutaneous penetration to be the most important route in poisoning of pesticide formulators and sprayers.[86] Topical contact with gamma benzene hexachloride was followed by urticaria,[3,87] eczema,[50,88] and in one case report, gamma benzene hexachloride mixed with chlorophenothane was followed by alopecia.[83] The cause and effect relationship between these last symptoms and gamma benzene hexachloride has not been established.

COMMENT

Although there is not total agreement about every aspect of gamma benzene hexachloride toxicity it is reasonably clear that the reported toxic effects of accidental poisoning in animals and humans bears a striking similarity to the rare anecdotal communications of complications in humans being treated for scabies with gamma benzene hexachloride lotion (headache, nausea, transient seizures). The recommendations for treatment of scabies with gamma benzene hexachloride includes its use after a hot soapy bath and a single application for 24 hours. However, the *minimum* requisite time of application resulting in a reasonable cure rate is not known. In 1948, Wooldridge[49] reported 95% of his patients were mite-free with the regimen recommended above, and the same regimen seems to have been advocated and used ever since by most practitioners treating scabies.

Although some aspects of the percutaneous absorption of gamma benzene hexachloride have been studied,[84,85] it is fallacious to assume that such data reflect its percutaneous penetrability in patients whose epidermal barrier has been damaged by chronic excoriation. The biological effects of equal doses of medications such as gamma benzene hexachloride may be greater in infants than in adults, but there are no pediatric dosage guidelines available. In fact, premature infants absorb greater amounts percutaneously. Certain areas of the body, such as the scrotum, appear to offer virtually no barrier to absorption. We have no clear evidence concerning the effects of gamma benzene hexachloride on embryonic tissue, particularly those of the human. Finally, the long-term effects of exposure are not well-known.

Considering the present data, and until more information becomes available about the specific treatment needs of scabies, the following observations and suggestions may have some merit.

1. Gamma benzene hexachloride should not be applied after a hot soapy bath. It seems unreasonable to increase percutaneous absorption of the substance when the organism to be attacked is in the epidermis. It should probably be applied on dry, cool skin. If a cleansing bath is to be taken, the skin should first be permitted to dry and cool. Cannon and McCrae[39] found the application to be quite effective without bathing.

2. Since we do not know how long we must apply gamma benzene hexachloride to effect a cure, the presently used regimen of application for 24 hours may be unnecessarily long if shorter contact time may be effective.

3. A concentration weaker than 1% may suffice, particularly for badly excoriated skin.

4. Commercially available 1% concentrations of gamma benzene hexachloride dosage forms should be used with extreme caution, if at all, in pregnant women, very small infants, and people with massively excoriated skin.

5. Recently, a gamma benzene hexachloride spray for the home environment has been marketed. There seems to be no demonstrated urgent need for such a spray. The spray itself may

pose unknown environmental hazards.

6. The use of gamma benzene hexachloride shampoo for pediculosis is probably relatively safe if the contact time is brief.

7. There are other available treatments for scabies, such as crotamiton and benzyl benzoate and sulfur, and these should be reconsidered when the patients are very young, pregnant, or badly excoriated.

8. Retreatment of patients with gamma benzene hexachloride should not take place before eight days and then only if active organisms can be demonstrated.

Finally, gamma benzene hexachloride is an effective agent against a major human health problem. Its potential for toxic effects should be recognized and since it remains unknown, the minimum appropriate dose needed to effect a cure needs to be determined.

PROBABLY WON'T CARRY FACE CLOTHS...
BUT THEY MIGHT CARRY

THERAPADS PLUS®

TO COMPLEMENT ANY ACNE REGIMEN

☐ CONVENIENT CLEANSING— ANYTIME, ANYWHERE

Therapads Plus provide effective cleansing and drying actions to remove excess surface oiliness... cleanse deeply, thoroughly, and antiseptically. Therapads Plus are pleasantly scented and saturated with a colorless solution of 70% ethyl alcohol, 1.5% salicylic acid, and 0.1% sodium alkyl aryl polyether sulfonate.

☐ HELP CONTROL OILY SKIN, BLACKHEADS, ACNE

Used 2 or 3 times a day—such as midmorning, midafternoon and bedtime—Therapads Plus help keep skin clean, and free from oil between soap and-water washings; also help dry existing blemishes.

Therapads Plus—available in boxes of 30 foil-wrapped pads. Therapads (regular)—available in jars of 40 and 100.

Perma Tweez®

ELECTROLYSIS FOR PERMANENT HAIR REMOVAL

Clinical study (copy on request) proves safety and efficacy of laity self-use electrolysis. Study shows chin and even axilla can be self-treated effectively through use of mirror. This permanent hair remover features the only patented self-correcting needle in existence. Battery operated instrument sterilizes itself when current flows. No-puncture safety feature also helps prevent infection.

Thousands of units sold to physicians for such varied application as removal of inverted eyelashes to cosmetic use.

PERMA TWEEZ & ATTACHMENT $22.45

Now, a dry skin lotion formulated to meet the exacting requirements of atopics

Carmol® Ten Lotion The Dry Skin Lotion with the Light Touch.
Carmol Ten Lotion relieves the itching and rough feel of dry skin; restores and retains the normal softness of skin.

Contains 10% Urea for its moisturizing action and cosmetic effect.
Lipid free, non-occlusive: contains no petrolatum, no mineral oil.
Hypoallergenic: contains no lanolin, parabens or other sensitizing preservatives.
Carmol Ten is available in pharmacies in 6 fluid ounce bottles.
Samples on request.

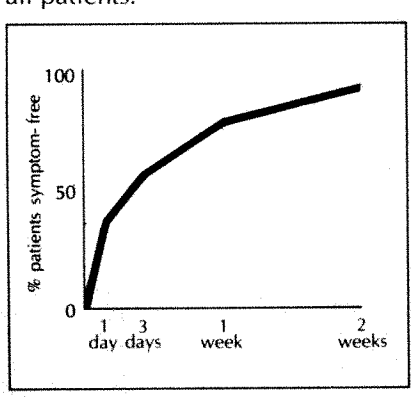
Ingram Pharmaceutical Company, San Francisco 94111 © IPC. 1976

The seven most important reasons to prescribe a topical antifungal. Right at your fingertips.

1 It is effective against the most prevalent fungal pathogens. MicaTin brand miconazole nitrate 2% offers exceptional effectiveness against the most difficult-to-treat pathogen—*Trichophyton rubrum*, and is equally effective against *Trichophyton mentagrophytes, Epidermophyton floccosum, Candida albicans* and *Malassezia furfur.*

2 It clears the most common fungal infections. MicaTin provides outstanding clinical and mycological efficacy in tinea pedis,* tinea corporis* and tinea cruris* as well as candidiasis and tinea versicolor.

3 It relieves symptoms quickly. Within 72 hours for the majority of patients. Within 1 to 2 weeks for virtually all patients.



4 It demonstrates effectiveness in extensive studies. Clinical studies† demonstrate the outstanding success rate of MicaTin in the treatment of tinea pedis, tinea corporis and tinea cruris, when used with the recommended dosage of twice daily for one month. At the end of therapy, 88—94% of the patients were clinically clear.

The clinical studies of patients with candidiasis and tinea versicolor are equally impressive. Nine out of ten patients with candidiasis or tinea versicolor were clinically and mycologically clear within two weeks—the recommended duration of treatment.

Pathogen	Infection	Conversion KOH	Culture	Clinical Clearance or Improvement
Trichophyton rubrum	Tinea pedis	82%	86%	88%
Trichophyton mentagrophytes / *Epidermophyton floccosum*	Tinea corporis / Tinea cruris	93%	90%	94%
Candida albicans	Candidiasis†	92%	86%	88%
Malassezia furfur	Tinea versicolor	89%	—	92%

5 Its low relapse rate promises an outstanding chance of cure. To prove how effective MicaTin really is in keeping fungal infections clear, we evaluated these same patients one month later (median).† Of the 121 patients who were clear of tinea pedis, tinea corporis and tinea cruris at the end of treatment *and* were available for follow-up, 92% showed no clinical or mycological recurrence of the original infection.

And of the 34 patients cleared of cutaneous candidiasis *and* available for follow-up, 91% were still clear two weeks later (median).

6 It has a low incidence of side effects. Reports of "burning" sensation, irritation and maceration with MicaTin have been few and isolated. Naturally, it should not be used in patients with known hypersensitivity to any of its ingredients.

7 It is economically priced. The retail price of MicaTin is usually lower than that of other prescription antifungals.

Introducing new
MicaTin Lotion
brand miconazole nitrate 2%
12 ml. and 30 ml. bottles

MicaTin cream
brand miconazole nitrate 2%
new 85 g. (3 oz.) tube
and familiar 1 oz. and 15 g. sizes

Description: MicaTin brand miconazole nitrate cream 2% and lotion 2% each contain miconazole nitrate‡ 2%, formulated into a water miscible base consisting of pegoxol 7 stearate, peglicol 5 oleate, mineral oil, benzoic acid, and butylated hydroxyanisole.

Actions: Miconazole nitrate is a synthetic antifungal agent which inhibits the growth of the common dermatophytes, *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* the yeast-like fungus, *Candida albicans,* and the organism responsible for tinea versicolor *(Malassezia furfur).*

Indications: For topical application in the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* in the treatment of cutaneous candidiasis (moniliasis), and in the treatment of tinea versicolor.

Contraindications: MicaTin has no known contraindications.

Precautions: If a reaction suggesting sensitivity or chemical irritation should occur, use of the medication should be discontinued.

For external use only. Avoid introduction of MicaTin brand miconazole nitrate cream 2% and lotion 2% into the eyes.

Adverse Reactions: There have been isolated reports of irritation, burning, and maceration associated with application of MicaTin.

Dosage and Administration: Sufficient MicaTin cream should be applied to cover affected areas twice daily (morning and evening) in patients with tinea pedis, tinea cruris, tinea corporis, and cutaneous candidiasis and once daily in patients with tinea versicolor. It is preferable to use MicaTin lotion in intertriginous areas; if the cream is used, it should be applied sparingly and smoothed in well to avoid maceration effects.

Early relief of pruritus (first week) and early clinical improvement (one to two weeks) have been seen in treatment of infections caused by common dermatophytes. Even though clinical improvement may be seen fairly soon after treatment is begun, *Candida* infections should be treated for two weeks and dermatophyte infections for one month in order to reduce the possibility of recurrence. If a patient shows no clinical improvement after a month of treatment, the diagnosis should be redetermined. Patients with tinea versicolor usually exhibit clinical and mycological clearing after two weeks of treatment.

How Supplied: MicaTin brand cream 2% containing miconazole nitrate at 2% strength is supplied in 1 oz., 15 g., and 3 oz. tubes. MicaTin brand lotion 2% containing miconazole nitrate at 2% strength is supplied in polyethylene squeeze bottles in quantities of 12 and 30 ml.

*When infecting organisms are *Trichophyton rubrum, Trichophyton mentagrophytes* and *Epidermophyton floccosum.*

†Data for tinea pedis is based on 4 weeks' therapy in 138 patients; for tinea cruris and tinea corporis—4 weeks' therapy in 50 patients; for tinea versicolor—2 weeks' therapy in 38 patients; for candidiasis—2 weeks' therapy in 23 patients and 4 weeks' therapy in 20 patients. (There was no significant difference in effectiveness between the two candidiasis groups.) Data on file, Dermatological Division, Johnson & Johnson.

AAD Task Force Report

Dermatologic Radiotherapy and Thyroid Cancer

Herbert Goldschmidt, MD

The increased risk of thyroid cancer in patients who received therapeutic doses of x-radiation to the head, neck, and upper part of the thorax for various nonmalignant conditions during infancy and childhood is well recognized. Recent publicity through articles in local newspapers and journals and announcements via radio and television has alarmed many patients who are aware of such irradiation. The Task Force on Ionizing Radiation of the National Program for Dermatology has been contacted by many colleagues requesting advice on the proper procedure to follow with patients who were treated in the past for benign skin conditions. Published recommendations by various specialists are contradictory, particularly concerning the benefits and risks of radioactive diagnostic procedures and the need for recall of irradiated patients. Recent statements by the National Cancer Institute and the American Thyroid Association, Inc, have helped considerably to clarify this situation.

Accepted for publication June 29, 1976.

From the Task Force on Ionizing Radiation of the National Program for Dermatology.

Reprint requests to Suite 620, One Bala-Cynwyd Plaza, Bala-Cynwyd, PA 19004 (Dr Goldschmidt).

The following recommendations are partially excerpted from the summary of a workshop, "Late Effects of Irradiation of the Head and Neck in Infancy and Childhood,"[1] held at the National Cancer Institute (NCI) in Bethesda, Md, in September 1975, which was attended by leading representatives of various medical specialties. The report from the workshop is the most authoritative statement on this matter and supersedes other recommendations. Similar recommendations were endorsed by the American Thyroid Association, Inc.[2]

Thyroid Cancer

Thyroid cancer is a relatively rare disease; it occurs twice as frequently in females as in males. The incidence increases with age. It is estimated that it will account for approximately 1,150 deaths in the United States in 1976 and that 8,100 new cases will be diagnosed. The age-adjusted rate of thyroid cancer in the United States in 1969-1971 was 3.7/100,000.[3] Autopsies of patients dying with no known thyroid disease have revealed small foci of cells that appear malignant in up to 5.7% of the glands.[3] The true incidence of thyroid cancer in *irradiated* individuals is therefore difficult to assess. There is no doubt, however, that the incidence of thyroid cancer is significantly increased in some patients 5 to 35 years after they received radiation therapy for various benign conditions during infancy and childhood, particularly for enlargement of the thymus, hypertrophy of tonsils and adenoids, cervical adenitis, mastoiditis, sinusitis, tinea capitis, hemangiomas, and keloids of the head and neck. The participants in the workshop agreed that only a small percentage of irradiated individuals develop thyroid tumors. Most of the tumors found have been benign, and most of those that are malignant have been well-differentiated papillary or follicular neoplasms or both, which grow slowly, metastasize relatively late, and are curable by surgery while still localized. (A relatively high incidence was found in a well-publicized study from Michael Reese Hospital in Chicago,[4,5] where 27% of 1,056 irradiated individuals recalled showed various thyroid abnormalities; thyroid carcinomas were found in 33% of 60 of the affected patients on surgical exploration.)

Thyroid Cancer and Dermatologic X-Ray Therapy

1. **Radiotherapy of Various Skin Conditions.**—The great majority of pub-

lished reports of thyroid abnormalities refer to radiation treatments of nondermatologic problems during infancy. Radiotherapy for dermatologic conditions is mentioned as a possible causative factor of such abnormalities in only a small number of patients.[4,6,7] Two large studies indicate an increased risk of thyroid nodules or thyroid cancer or both in children treated for tinea capitis with very penetrating radiation qualities.[8,9] Indiscriminate radiotherapy of hemangiomas and other benign skin diseases of the neck region during infancy and early childhood is clearly associated with an increased risk to the thyroid gland. Most of these indications are obsolete now and require no further discussion. Patients who were treated for these conditions in the past should be followed up as described below. The only remaining indication for radiotherapy in young age groups is the treatment of selected cases of acne[10]; other indications must be exceedingly rare.

2. **Radiotherapy of Acne *Without* Radiation Protection.**—Dermatologists have been using radiation protection measures for several decades. During radiotherapy of acne, cones are employed by most dermatologists to reduce scatter radiation to the thyroid and other body regions; a lead shield over the thyroid area serves to further reduce unnecessary exposure.

A different situation exists in patients who were treated without the benefits of cones or thyroid shields or both, particularly when the neck area was deliberately or inadvertently exposed to full therapeutic doses. Because of the increased risk of thyroid abnormality, these patients should be examined every two years. This also applies when accurate records of radiation exposure are not available.

3. **Radiotherapy of Acne With Radiation Protection.**—Is radiotherapy of acne associated with an increased risk to the thyroid gland when modern radiation protection measures are used and relatively superficial radiation qualities are applied? The Task Force on Ionizing Radiation believes that presently available statistical data[4,6,7] are insufficient to substantiate a causative relationship and suggests further in-depth studies to clarify this problem. Since no other equally effective form of treatment was available, radiotherapy was given to a large number of dermatological patients until 1950; the occurrence of thyroid cancer in a very limited number of these irradiated patients could therefore be coincidental. It is also conceivable that the biological effects of small fractionated weekly doses of ionizing radiation reaching more mature thyroid tissue are significantly less hazardous than those observed following radiotherapy with one or two high doses directly to the thyroid region during infancy and early childhood. Few dermatologists treated acne with x-radiation before the age of 16 to 18 years when the thyroid is considered to be fully developed and less radiosensitive.[1] Even more important is the fact that the majority of dermatologists have used cones to reduce scatter radiation even before 1950. The effectiveness of cones in dermatologic x-ray therapy has been demonstrated by thermoluminescence dosimetry.[11] Many dermatologists also have applied lead shields routinely to the thyroid region for additional protection. Compared to diagnostic roentgenographic methods, the dose reaching the thyroid is extremely small when proper radiation protection measures are used.[11]

Identification of Patients

Although the participants in the NCI workshop agreed that it would be desirable to recall for examination every patient who received radiation therapy, they concluded that, for the most part, this would be logistically impossible. It is estimated that there are over 1 million individuals in the United States who have been irradiated for benign conditions in the head and neck areas[12]; in many instances radiation records are no longer available or patients have moved and are difficult or impossible to locate. The NCI group felt that recall efforts should be encouraged but that a low-keyed public education program would be more appropriate. This program should educate the public about the problem, stressing the need for medical examination, the low incidence of cancer, and the high probability of cure.

Diagnostic Measures

The main recommendation of the NCI consultants was that all individuals with a history of head or neck irradiation should be examined periodically (at least every two years) indefinitely.

Most patients with radiation-related thyroid tumors are asymptomatic. Inspection and palpation of the thyroid gland are the two most important measures of the clinical evaluation. The presence of a palpable nodule is the most conclusive evidence of a thyroid abnormality. Only a small percentage of palpable tumors show malignant changes. Most tumors grow very slowly and metastases are rare and usually occur late. Laboratory studies are less important than clinical findings. The majority of workshop participants concluded that a thyroid scan is *not mandatory,* if palpation of the gland by an experienced examiner reveals no abnormalities. In the absence of palpable abnormalities, careful re-examination is recommended at least every two years.

When the palpation of the thyroid reveals one or more firm, discrete nodules, the majority of consultants believed that these should be removed surgically. They agreed that radioisotope scans contribute little useful information and that most discrete nodules should be removed without consideration of a scan. (Some specialists disagree with this view and recommend thyroid imaging procedures on all patients with a history of irradiation, whether or not palpable nodules are present. The new technetium Tc 99m scintigram is far safer [estimated dose to the adult thyroid: 0.1 rad][13,14] than the older and still widely used radioactive imaging procedure with ^{131}I, which delivers a relatively high radiation dose [100-200 rads]).

Current Use of Dermatologic Radiotherapy for Benign Conditions

Ionizing radiation has been used in the treatment of benign diseases by

many medical specialties. The growing awareness of potential side effects has led to the recognition that in most instances radiotherapy should be limited to diseases where other forms of treatment have failed or are expected to fail. The advisability of continuing radiotherapy for certain benign diseases by various medical specialties, and the potential risks of ionizing radiation therapy are presently being investigated by a committee of the National Academy of Sciences/National Research Council, which includes radiotherapists, radiobiologists, radiophysicists, epidemiologists, geneticists, thyroid specialists, pediatricians, thyroid surgeons, ophthalmologists, and dermatologists. The Task Force on Ionizing Radiation is planning to issue guidelines for dermatologic radiotherapy, based on the recommendations of this committee. These guidelines will summarize modern indications and techniques and describe appropriate radiation protection measures. Until then radiotherapy for benign skin conditions should be given only with proper radiation protection (cones; eye, thyroid, and gonad shielding). The least penetrating, effective radiation qualities (eg, grenz rays) should be preferred and doses should be limited to the smallest effective individual and total dose.

Desquam-X5®

Desquam-X10®

CONTENTS: Desquam-X 5 contains 5% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

Desquam-X 10 contains 10% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

INDICATION: A topical aid for the control of acne vulgaris.

ACTION: Provides the desirable drying and desquamation needed in the topical treatment of acne. Desquam-X has been demonstrated to have anti-bacterial effects, especially against Corynebacterium acnes.

DIRECTION FOR USE: After washing as instructed, rub Desquam-X into affected areas twice daily. In fair-skinned individuals or under excessively dry atmospheric conditions it is suggested that therapy be initiated with one application daily. The desired degree of drying and peeling can be obtained by modification of the dosage schedule.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Desquam-X.

PRECAUTIONS: Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medication out of the reach of children.

NOTE: May bleach colored fabrics.

HOW SUPPLIED: Plastic tubes 1.5 oz. (42.5 gm.)

CAUTION: Federal law prohibits dispensing without prescription.

AVEENO®
Colloidal Oatmeal
bath for sensitive skin

When you treat inflammatory diseases, such as wet dermatitis (including allergic, atopic and contact), intertrigo or wet pruritus, a colloidal oatmeal bath may prove valuable, adjunctive therapy.

Soak Away The Discomfort With AVEENO COLLOIDAL OATMEAL.

- **Cleans naturally**—a soap-free way to absorb dirt and excess oil.
- **Comforts gently**—soothingly soaks hard-to-reach and widespread problem areas.
- **Long-lasting protection**—colloidal oatmeal film continues to protect after bathing.
- **Helps restore normal skin pH.**

Available in 1 lb. and 4 lbs. boxes.

Cooper Laboratories, Inc., Wayne, N.J. 07470 Cooper

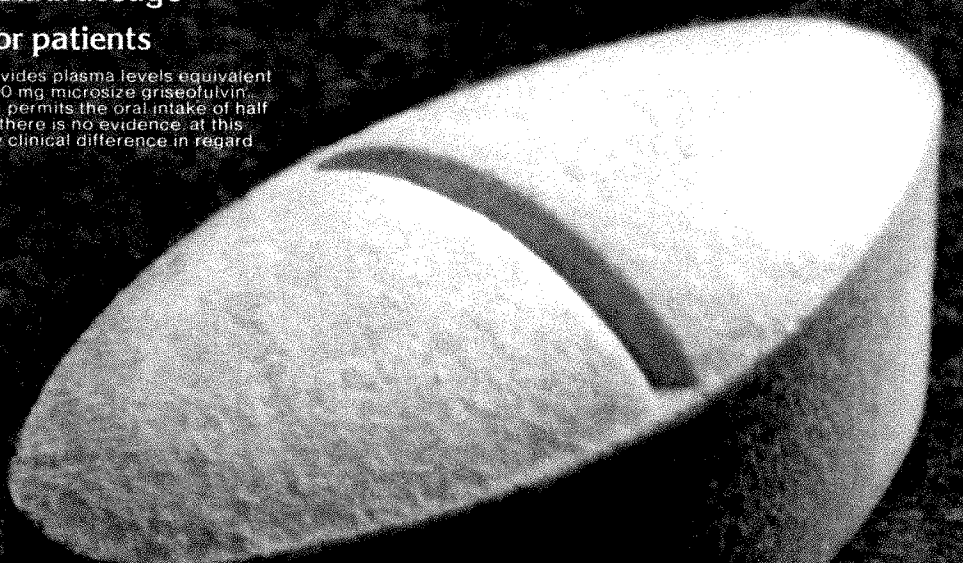
CUT THE GRISEOFULVIN DOSE IN HALF

Gris-PEG®
(griseofulvin ultramicrosize)
Tablets 125 mg

For fungal infections sensitive to griseofulvin

- Only half the dose required*
- Absorption nearly complete without fatty meals
- Once-a-day or b.i.d. dosage
- Reduced cost for patients

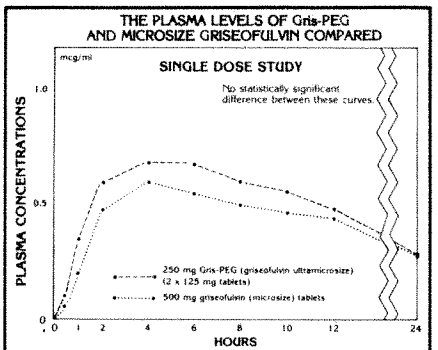
*250 mg of Gris-PEG® provides plasma levels equivalent to those obtained with 500 mg microsize griseofulvin. This improved absorption permits the oral intake of half as much griseofulvin but there is no evidence, at this time, that this confers any clinical difference in regard to safety or efficacy.



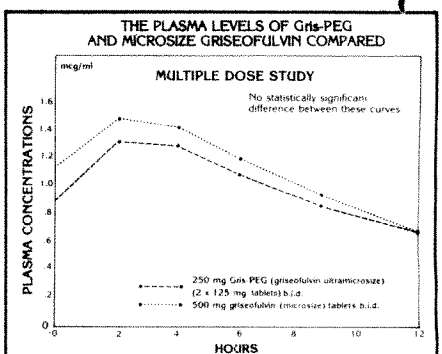
Dorsey LABORATORIES
Division of Sandoz Inc.
LINCOLN, NEBRASKA 68501

Please see other side for full prescribing information

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
The ½ dose griseofulvin.



Based on a single dose double-blind bioavailability study conducted in 24 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels. There is no significant difference between peak plasma levels, times to peak, and areas under the curve. Gas chromatographic assay.



Based on a double-blind multiple dose steady state crossover bioavailability study conducted in 17 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels obtained on days 9, 11 and 13. There is no significant difference between times to peak, peak plasma levels, and areas under the curve. Gas chromatographic assay.

DESCRIPTION

Griseofulvin is an antibiotic derived from a species of *Penicillium*.

Gris-PEG is an ultramicrocrystalline solid-state dispersion of griseofulvin in polyethylene glycol 6000.

Gris-PEG tablets differ from griseofulvin (microsize) tablets USP in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsize griseofulvin.

ACTION

Microbiology: Griseofulvin is fungistatic with *in vitro* activity against various species of *Microsporum, Epidermophyton* and *Trichophyton*. It has no effect on bacteria or other genera of fungi.

Human Pharmacology: The peak plasma level found in fasting adults given 0.25 g of Gris-PEG occurs at about four hours and ranges between 0.37 to 1.6 mcg/ml.

Comparable studies with microsize griseofulvin indicated that the peak plasma level found in fasting adults given 0.5 g occurs at about four hours and ranges between 0.44 to 1.2 mcg/ml.

Thus, the efficiency of gastrointestinal absorption of the ultramicrocrystalline formulation of Gris-PEG is approximately twice that of conventional microsized griseofulvin. This factor permits the oral intake of half as much griseofulvin per tablet but there is no evidence, at this time, that this confers any significant clinical differences in regard to safety and efficacy.

Griseofulvin is deposited in the keratin precursor cells and has a greater affinity for diseased tissue. The drug is tightly bound to the new keratin which becomes highly resistant to fungal invasions.

INDICATIONS

Gris-PEG (griseofulvin ultramicrosize) is indicated for the treatment of the following ringworm infections.

Tinea corporis (ringworm of the body)
Tinea pedis (athlete's foot)
Tinea cruris (ringworm of the thigh)
Tinea barbae (barber's itch)
Tinea capitis (ringworm of the scalp)
Tinea unguium (onychomycosis; ringworm of the nails)

when caused by one or more of the following genera of fungi:

Trichophyton rubrum
Trichophyton tonsurans
Trichophyton mentagrophytes
Trichophyton interdigitalis
Trichophyton verrucosum
Trichophyton megnini
Trichophyton gallinae
Trichophyton crateriform
Trichophyton sulphureum
Trichophyton schoenleini
Microsporum audouini
Microsporum canis
Microsporum gypseum
Epidermophyton floccosum

NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.

The use of the drug is not justified in minor or trivial infections which will respond to topical agents alone.

Griseofulvin is *not* effective in the following:

Bacterial infections
Candidiasis (Moniliasis)
Histoplasmosis
Actinomycosis
Sporotrichosis
Chromoblastomycosis
Coccidioidomycosis
North American Blastomycosis
Cryptococcosis (Torulosis)
Tinea versicolor
Nocardiosis

CONTRAINDICATIONS

This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.

WARNINGS

Prophylactic Usage: Safety and Efficacy of Griseofulvin for Prophylaxis of Fungal Infections Has Not Been Established.

Animal Toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.

In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.

Usage in Pregnancy: The safety of this drug during pregnancy has not been established.

Animal Reproduction Studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.

Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

PRECAUTIONS

Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic and hematopoietic, should be done.

Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.

Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.

Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.

Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

ADVERSE REACTIONS

When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion and impairment of performance of routine activities.

Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.

When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

DOSAGE AND ADMINISTRATION

Accurate diagnosis of the infecting organism is essential. Identification should be made either by direct microscopic examination of a mounting of infected tissue in a solution of potassium hydroxide or by culture on an appropriate medium.

Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. Representative treatment periods are—*tinea capitis*, 4 to 6 weeks; *tinea corporis*, 2 to 4 weeks; *tinea pedis*, 4 to 8 weeks; *tinea unguium*—depending on rate of growth—fingernails, at least 4 months; toenails, at least 6 months.

General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required particularly in treatment of *tinea pedis*. In some forms of athlete's foot, yeasts and bacteria may be involved as well as fungi. Griseofulvin will not eradicate the bacterial or monilial infection.

An oral dose of 250 mg of Gris-PEG (griseofulvin ultramicrosize) is biologically equivalent to 500 mg of griseofulvin (microsized), USP (see ACTION Human Pharmacology).

Adults: A daily dose of 250 mg will give a satisfactory response in most patients with *tinea corporis, tinea cruris* and *tinea capitis*. One 125 mg tablet twice per day or two 125 mg tablets once per day is the usual dosage. For those fungal infections more difficult to eradicate such as *tinea pedis* and *tinea unguium*, a divided daily dose of 500 mg is recommended. In all cases, the dosage should be individualized.

Children: Approximately 5 mg per kilogram (2.5 mg per pound) of body weight per day is an effective dose for most children. On this basis, the following dosage schedule for children is suggested:

Children weighing over 25 kilograms (approximately 50 pounds)—125 mg to 250 mg daily.

Children weighing 15-25 kilograms (approximately 30-50 pounds)—62.5 mg to 125 mg daily.

Children 2 years of age and younger—dosage has not been established.

Dosage should be individualized, as is done for adults. Clinical experience with griseofulvin in children with *tinea capitis* indicates that a single daily dose is effective. Clinical relapse will occur if the medication is not continued until the infecting organism is eradicated.

HOW SUPPLIED

Gris-PEG (griseofulvin ultramicrosize) Tablets (white) differ from griseofulvin (microsize) tablets (USP) in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsized griseofulvin. Two 125 mg tablets of Gris-PEG are biologically equivalent to 500 mg of microsized griseofulvin. In bottles of 100 and 500 scored, film-coated tablets.

News and Notes

Institute in Immunologic Diagnosis.—An "Advanced Institute in Methods of Immunological Diagnosis," conducted under the auspices of the World Health Organization Collaborating Laboratory for the Serology of Autoimmune Diseases at Wayne State University School of Medicine, will be held June 15-24, 1977 at the Cranbrook Educational Community in Bloomfield Hills, Mich. The course will present an up-to-date survey of current immunological methods applicable to the diagnosis of human immunological diseases. Category 1 credit for postgraduate medical education has been approved. Deadline for receiving applications is April 15. Further information can be obtained by writing to Noel R. Rose, MD, PhD, Department of Immunology and Microbiology, Wayne State University School of Medicine, 540 East Canfield, Detroit, MI 48201.

The University of California, San Francisco-Cleveland Clinic Seminar in Maui.—The second annual University of California, San Francisco-Cleveland Clinic Seminar will be held at the Hotel Intercontinental in Maui from Jan 20 to 25, 1978. The program will stress advances in dermatologic sciences most relevant to patient care. For information about registration, please write the Department of Dermatology at either the Cleveland Clinic, 9500 Euclid Ave, Cleveland, OH 44106 or the University of California, San Francisco 94143.

Advanced Seminars in Dermatology.—The annual Advanced Seminars in Dermatology will be held in Monterey, Calif, from Wednesday through Sunday Sept 14 through 18, 1977. In addition to the faculty of the University of California Medical School, San Francisco, there will be guest speakers. A partial list includes Drs Thomas Fitzpatrick, Henry Roenigk, and E. Krull. For information please write the Skin Disease Research Foundation, c/o Charlotte Sandoval, PO Box 27534, San Francisco, CA 94127.

Eastern Regional Meeting of the Society for Investigative Dermatology.—The next eastern regional meeting of the Society for Investigative Dermatology, Inc, will be held on Sunday morning, May 8, 1977 at the Waldorf-Astoria Hotel, New York City. Address all inquiries to Alan R. Shalita, MD, Downstate Medical Center, Division of Dermatology, 450 Clarkson Ave, Brooklyn, NY 11203.

Clinical Teaching Slides.—The American Academy of Dermatology and the Institute for Dermatologic Communication and Education have prepared another collection of clinical teaching slides. The fourth set of 50 slides, a broad collection of *Skin Tumors*, is now available. The fee for the slides is $35 (Illinois residents add 5% sales tax; outside the United States and Canada, add $6). The first three sets of 50 slides, *Pediatric Dermatoses*, *Some Common Dermatoses*, and *Cutaneous Manifestations of Systemic Disease*, are available at the same price. Interested parties can obtain these sets directly from the American Academy of Dermatology, PO Box 552, Evanston, IL 60204. Your check or money order must accompany your order.

Samitz Lectorship.—The Department of Dermatology of the University of Pennsylvania School of Medicine announces the second M. H. Samitz Lectureship. Herman N. Eisen, MD, professor of immunology, Cancer Research Center, Massachusetts Institute of Technology, will present "Specificity of Cell-Mediated Immune Reactions" Friday, April 22, 1977 at 4 o'clock in the Medical Alumni Hall of the Hospital of the University of Pennsylvania. There will be a reception following the lecture.

Atlantic Dermatological Conference.—The next meeting of the Atlantic Dermatological Conference will be held at the Waldorf-Astoria Hotel, New York City, Friday and Saturday, May 6 and 7, 1977. Address all inquiries to Peter Lombardo, MD, 120 E 64th St, New York, NY 10021.

Scleroderma Research Award for 1977.—The Monterey Bay Scleroderma Foundation announces its first $1,000 annual Award for Scleroderma Research for 1977. The establishment of an award carries with it the hope that it will act as an incentive to study this chronic disabling disease.

The award is designed for the individual or group whose investigative work in this field has been outstanding. Names of applicants for the award, together with supporting data should be submitted for consideration by Dec 1, 1977. Results of the research must have been presented at a scientific medical meeting or published in a recognized medical journal.

The award recipient will be determined by a committee of five men. If,

in the committees' opinion, none of the applications reflects outstanding research, no award will be given for that year. Address all communications to Denny L. Tuffanelli, MD, Department of Dermatology, University of California, School of Medicine, San Francisco, CA 94143.

Symposium.—"Diagnosis of Inflammatory Skin Diseases: Histologic, Electron Microscopic, and Immunologic Aspects," directed by Dr A. Bernard Ackerman and sponsored by the Departments of Dermatology and Pathology of the New York University Medical Center, will be conducted from 9:00 AM, Thursday, Oct 13, to 12:00 PM, Saturday, Oct 15, 1977, at the New York University Medical Center.

This symposium deals with the diagnosis of inflammatory diseases of the skin by light microscopy, electron microscopy, and immunology. Special attention will be given to those diseases that are better recognized and understood by means of electron microscopy and immunologic study. Also, the function of inflammatory cells in diseases of the skin will be emphasized.

Each general subject will be moderated by a histopathologist who will call on electron microscopists and immunologists for further elucidation of appropriate topics. The format will be brief presentations of particular subjects by particular members of the faculty, followed by discussion first by the entire faculty, and then by the audience with the faculty responding.

The faculty is as follows: histology: Drs A. Bernard Ackerman, John Headington, John Maize, Arkadi Rywlin; electron microscopy: Drs Michael Heaphy, Elaine Waldo, Helmut Wolff; immunology: Drs Frank Austen, Rudolf Baer, Gunter Burg, Jean-Claude Bystryn, Stephen Katz, H. Sherwood Lawrence, William Meigel, Thomas Provost, Dorothy Zucker-Franklin.

Further details may be obtained from the Office of the Associate Dean, New York University Postgraduate Medical School, 550 First Ave, New York, NY 10016.

CORRECTIONS

In the article "Corticosteroid-Induced Cutaneous Atrophy and Telangiectasia," which appeared in the August issue of the ARCHIVES (112:1115-1117, 1976), **Fig 1** (p 1116) **was reversed.** The larger animal (control) should have been on the far left instead of the right.

Typesetting Error.—In the article "Chronic Bullous Dermatosis of Childhood," published in the January issue of the ARCHIVES (113:42-46, 1977), the introductory paragraph of the article should have been set as the last paragraph of the abstract.

SOLVED

SYNALAR® TOPICALS

FLU[illegible]NIDE

Treat Sensitive, Irritated, Stubborn, Pustular Acne **Gently!**

Soft as a Fleecy Cloud.

SULFACET-HC®

Sodium Sulfacetamide 10%, Hydrocortisone Alcohol ½%, Sulfur Colloid 5%.

Drying without Irritation.

SULFACET-HC*— unsurpassed anti-microbial and anti-seborrheic acne lotion.

DESCRIPTION (As Dispensed)

Hydrocortisone	0.5%W/V
Sodium Sulfacetamide	10.0%W/V
Sulfur Colloid	5.0%W/V

in a water-washable lotion containing purified water, zinc oxide, talcum, propylene glycol, titanium dioxide, natural clays, fatty acid amide, iron oxides, ethoxylated esters, natural and synthetic gums, organic salts, sodium chloride and bisulfite, sequestrant, butyl and methyl parabens and 2-Bromo-2-nitropropan-1,3-diol.

ACTIONS — Keratolytic, peeling, drying and antiseborrheic action.

INDICATIONS — Acne vulgaris, acne rosacea and seborrheic dermatitis.

CONTRAINDICATIONS — Topical steroids are contraindicated in viral diseases of the skin such as varicella and vaccinia. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired or in patients with kidney disease or those who have previously exhibited sensitivity to sulfonamides.

WARNINGS — USAGE IN PREGNANCY: Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients or in large amounts or for prolonged periods of time.

PRECAUTIONS — For External Use Only. Keep Away From Eyes. Sensitivity to sulfacetamide may occur. Caution and careful supervision should be observed when prescribing these drugs for patients who may be prone to hypersensitivity to topical sulfonamides, particularly if areas of denuded or abraded skin are involved. If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of the appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

ADVERSE REACTIONS — The following local adverse reactions have been reported with topical corticosteroids, either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation. Hypersensitivity to the sulfonamides indicated by previous toxic reaction such as agranulocytosis, acute hemolytic anemia, purpura hemorrhagica, drug fever, jaundice or contact dermatitis.

DOSAGE AND ADMINISTRATION — Apply a small quantity to the affected areas two to three times daily. The skin should be thoroughly cleansed and applications blended in with light massaging. Consult physician for advice on diet and other factors in control of acne.

HOW SUPPLIED — Lotion, bottles, 1 oz. and 2 oz. as dispensed.

CAUTION — Federal law prohibits dispensing without prescription.

An Unusual Variant of Darier Disease

Fig 1.

Fig 2.

Fig 3.

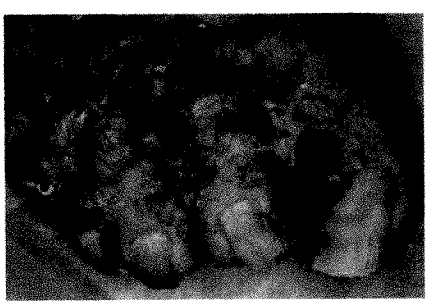

Fig 4.

To the Editor.—The article by Peck et al (112:495, 1976), reporting the cornifying variant of Darier disease was most interesting. The variant is not unique in the usual meaning of the word, for the authors refer to a second similar case found in the literature.

We have been following a patient with a cornifying variant of Darier disease for over ten years.

Report of a Case.—A 35-year-old man came to the dermatology clinic because of painful, malodorous vegetations on the lower legs. Lesions typical of the disease, both clinically and histologically, were present on his trunk, arms, and legs. His secondary infection cleared with tetracycline and acetic acid compresses. He was then lost to follow-up for 11 years, when he again returned because of painful, malodorous legs. Verrucous cornifying growths were present on the sides of the lower part of his legs (Fig 1 and 2), and the dorsum of his feet (Fig 3) and toes (Fig 4). Most of these areas were tender, malodorous, and a purulent discharge was present. Typical hyperkeratotic papules were present on the thorax, arms, and legs.

This is apparently the third reported case of this unusual variant of Darier disease.

JAMES F. DOLEZAL, MD
Iowa City

Discoid Lupus Erythematosus and the Variant Form of Hereditary Angioedema

To the Editor.—There are a number of reports in the literature of patients who, in association with connective tissue disease, have deficiencies of one or another component of the complement system. Recently Kohler et al[1] reported identical male twins with longstanding discoid lupus erythematosus (LE) and hereditary angioedema with C1 inhibitor (C1 INH) deficiency and a marked secondary decrease in C4.

Two genetic forms of hereditary angioedema have been described, the common and variant forms.[2] About 85% of patients have the common form. Immunochemical and functional concentrations of C1 INH in these patients range from undetectable to about 50% of normal. The remaining 15% of patients have the variant form of the disease; that is, normal or increased levels of an antigenically identical, but functionally deficient protein.[3] We recently have had the opportunity to study a patient with classical discoid LE and the variant form of hereditary angioedema.

Report of a Case.—The patient, a 49-year-old woman, had urticaria since childhood, associated with swelling of the hands, difficulty in swallowing, and stomach pains. She had been studied at the University of Cincinnati and a diagnosis of hereditary angioneurotic edema was made by Virginia Donaldson, MD. Her maternal grandmother and son also had hereditary angioneurotic edema.

Her main concern when I saw her was the cosmetic problem of scarring alopecia. She had extensive cutaneous lupus involving her face, scalp, and hands, which had not responded to therapy. She had no clinical evidence of systemic lupus.

Complement studies revealed total hemolytic complement at 17 CH_{50} units (normal, 25-42), C3 by immunodiffusion 120 (normal, 70-160), serum C4 assay 80,000 (normal, 242,000 to 1 million). Biopsy of an involved skin lesion showed granular deposition of IgG in the dermal epidermal zone. A biopsy specimen of uninvolved skin showed no abnormalities. Studies for C1 INH were done by Neal R. Cooper, MD, at the Scripps Clinic. Her sera contained normal levels of C1 INH protein. She had very low levels of C1 INH activity and a diagnosis of the variant form of hereditary angioedema was made. Her antinuclear antibody gave a positive reaction by a 1 to 160 speckled pattern. Anti-DNA and anti-ENA were not present.

Comment.—The occurrence of discoid LE and hereditary angioedema in

a patient with C1 INH and C4 deficiency seems significant. Demonstration of IgG at the dermal epidermal junction in the cutaneous lesions and the presence of apparently normal levels of C1 INH protein but very low levels of C1 INH activity were of added interest.

Furosemide-Induced Cutaneous Necrotizing Vasculitis

To the Editor.—We would like to report a case of cutaneous necrotizing vasculitis that was presumably induced by an allergic reaction to furosemide.

Report of a Case.—A 72-year-old white man with a past history of an anterior myocardial infarction, congestive heart failure, pacemaker insertion, mild renal insufficiency, and duodenal ulcer was referred to University Hospitals from a nursing home with a four-day history of purpuric skin lesions and blood-tinged sputum. His medications at the time of admission included daily doses of furosemide (40 mg) for at least the past five months and digoxin (0.25 mg).

On admission, physical examination revealed bibasilar pulmonary rales, a liver palpable 8 cm below the right costal margin, edema of both legs (3+), and a functioning cardiac pacemaker. The patient was responsive, but demented, with positive grasp and snout reflexes. The left pupil was nonreactive with vertical nystagmus noted on horizontal gaze. Bruits were appreciated over his left carotid artery and bilaterally over his femoral arteries. Examination of the skin revealed several, clear, bullous skin lesions on a hemorrhagic base located over the legs and ankles with multiple petechial lesions distributed over the legs, arms, palms, soles, trunk, and buccal mucosa (Fig 1).

Laboratory studies included a hematocrit reading of 35%; WBC count, 6,000/cu mm, with 87% polymorphonuclear leukocytes, 3% band cells, 7% lymphocytes, and 3% monocytes; platelets, 185,000/cu mm; total protein, 5.9 gm/100 ml; albumin, 2.5 gm/100 ml; and the chest x-ray film showed severe cardiomegaly. The clotting studies, Coombs test, tests for fibrin split products and antinuclear factor, lupus erythematosus preparation, and cultures of

Fig 1.—Bullous lesions on a hemorrhagic base located on the lower leg.

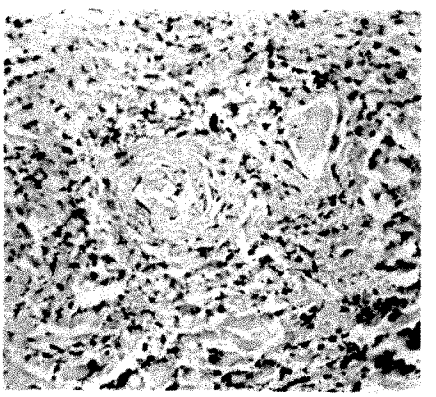

Fig 2.—Leukocytoclastic vasculitis with involvement of the deep dermal blood vessels (hematoxylin-eosin, ×250).

the blood, urine, sputum, cerebrospinal fluid, and skin were all normal. A skin biopsy specimen demonstrated a leukocytoclastic vasculitis with involvement of the blood vessels in the lower dermis (Fig 2). Direct immunofluorescence of the skin showed positive fluorescence of the blood vessels with anti-IgG, anti-IgA, anti-IgM, and anti-complement.

On the suspicion of systemic necrotizing vasculitis secondary to an allergic drug reaction, furosemide therapy was discontinued, and treatment with hydrocortisone (80 mg intravenously every six hours), ethacrynic acid (50 mg daily), and penicillin (2.5 million units every six hours) was started. The next day the patient appeared better, with resolution of some of the skin lesions. On the third day of hospitalization, however, he suffered a massive right cerebral infarction with left hemiparesis. Intravenous administration of dexamethasone was started, but the patient never regained consciousness and died five days later.

At autopsy, severe arteriosclerotic cardiovascular disease was found, with a recent right cerebral hemispheric infarction secondary to an embolus in the right middle cerebral artery. Examination of the vasculature of the kidneys and brain failed to show any signs of vasculitis.

Comment.—Necrotizing vasculitis has been associated with allergic drug reactions, collagen vascular disease, malignancy, cryoglobulinemia, macroglobulinemia, and infection. In light of the essentially negative findings of the laboratory evaluation of this patient, one must suspect an allergic drug reaction as the cause of his hemorrhagic, bullous eruption.

Hemorrhagic bullae on the lower extremities have been reported previously in a 65-year-old man taking digoxin, erythromycin, and furosemide.[1] The skin biopsy specimen in that case was interpreted as showing erythema multiforme. Bullous pemphigoid has also been reported after furosemide therapy.[2] We could find no reports, however, of a leukocytoclastic vasculitis following treatment with furosemide. Sulfonamides, on the other hand, have been reported to produce a sensitivity vasculitis,[3] and even a periarteritis nodosa-like picture. Since furosemide is a sulfonamide, it is postulated that furosemide was the inciting agent in this case of cutaneous necrotizing vasculitis.

Nomenclature of Antibiotics

To the Editor.—In reference to the recent article by Pablo and Fulton (111:734-735, 1975), it should be pointed out that chlortetracycline hydrochloride is marketed as Aureomycin (Lederle), while Achromycin (Lederle) is a brand name for tetracycline hydrochloride.[1] This raises the question as to whether the authors inadvertently studied the same antibiotic twice or simply confused their nomenclature.

In the letters to the editor that follow, reactions apparently induced by the fabric softener, Bounce, are noted. Initial letters from Donald H. Huldin, MD, received in November 1975 and Jerome Z. Litt, MD, in February 1976 were not accepted due to my misjudgment. Subsequently, Dr Litt published his account (Cutis 18:134, 1976). *Though the exact relationships and mechanisms involved in these responses are not clear, the time sequences reported strongly suggest specific associations. Because Bounce and perhaps other similar agents may be responsible for adverse reactions, we believed that this information should be made available to the readers of the* ARCHIVES. *We have asked James E. Weaver, PhD, to present the manufacturer's point of view in response to these reports.*—ED.

Side Effects of Bounce

To the Editor.—Up to now I have seen four cases of an acute contact dermatitis that appear to have been caused by Bounce, a fabric softener used in the drier. Two patients who wore T-shirts developed their rash in the underarm area, and two patients who wore jockey shorts developed their rash on the anterior abdomen.

Onset coincided with the first-time use of this product, and clearing occurred rapidly with its discontinuance and with treatment with 1% hydrocortisone cream. A careful history eliminated other causes. In one instance, the Bounce was used to impart a pleasant odor to the garments by placing it between the layers of clothing in a drawer.

This is another product with side effects.

CHARLES SHEARD, MD
Stamford, Conn

To the Editor.—About one year ago, complimentary samples of Bounce, a new fabric softener, were sent to physicians in this area. The product consists of sheets of nonwoven rayon impregnated with a perfume and two softening agents, dialkyldimethylammonium methyl sulfate and a fatty acid ester of a polyhydric alcohol.[1] The sheets are added to the clothes drier, and the warmth and tumbling action is said to release the ingredients. Four patients have been seen with symptoms that we believe were exacerbated by this new fabric softener.

Report of Cases.—A 2-year, 10-month-old boy was seen for a dermatitis of several weeks' duration that had been unresponsive to penicillin. The patient had a chronic recurrent nasal congestion, and there was a family history of allergy. The mother, a physician's wife, had recently used the new product. A severe erythematous scaly dermatitis on the flexors and small erythematous papules on the trunk were noted. The dermatitis cleared on treatment with systemic steroids, and the patients skin has remained clear with no further exposure to the product.

A 9-month-old girl was hospitalized for a facial dermatitis and respiratory distress of coughing, wheezing, and congestion. The patient had been in excellent health, except for one episode of bronchitis one month prior to admission. The mother, who has asthma and allergies, had recently used the fabric softener in the clothes drier but stopped it the day before admission. The dermatitis consisted of small erythematous papules and diffuse erythema on both cheeks. Complete blood cell count and temperature were normal, and chest roentgenograms showed inflammatory changes. The child's symptoms cleared while she was hospitalized, and she was discharged and seen three months later with no further difficulty since discontinuing use of the product.

A 4-month-old boy was hospitalized for treatment of respiratory distress with coughing, choking, and tachypnea. The infant had recently been exposed to viral respiratory infection, and there was a family history of respiratory allergy. Chest roentgenograms showed a right perihilar infiltrate consistent with bronchial pneumonia. Nasal pharyngeal culture grew no pathogenic organisms, and a WBC count and differential were normal. No dermatitis was present. Treatment consisted of amoxicillin and a mist tent, and seven days later the infant was discharged; he was still wheezing slightly, but he was otherwise asymptomatic and comfortable. Three weeks later, the infant was still wheezing, but results of a repeat chest roentgenogram were normal. Inspiratory wheezing in an infant who looked well was the only finding. The mother suspected the fabric softener was responsible and discontinued using it. Within a few days the wheezing stopped and has never recurred.

A 21-year-old woman was seen for a dermatitis of four months' duration. Although a family history of allergies was noted, the patient was in excellent health. Her mother had recently begun to use the fabric softener. A mild erythematous papular dermatitis on the anterior part of the thighs, antecubitals, and upper part of the back was noted. She received topical steroids, and her skin has remained clear since discontinuing use of the product.

Comment.—Dermatologic testing carried out by the manufacturer has shown no toxicity.[1] However, the literature reports four patients with bronchial asthma after exposure to the fabric softener.[2,3] Others have noted an increasing incidence of a generalized pruritis and dermatitis.[4] Many families may be exposed to this new fabric softener, and physicians should be alerted.

DONALD E. HAZELRIGG, MD

4. Litt JZ. Letter to the editor. *Cutis* 18:134, 1976.

To the Editor.—The Midwest has recently been used as a marketing area for a new antistatic laundry agent labeled Bounce. Many physicians received this free sample through the mail, along with a flier that described its nontoxic, benign nature in reference to dermatologic complaints. Many of the homes in the Midwest have also received complementary samples of this agent.

We have noted five contact dermatitis cases that we believe are directly related to this preparation being used in the care of the clothing. These are characterized by papular and pseudovesicular eruptions over the covered parts of the body. I was also impressed with the erythema that certain patients demonstrated in association with the primary lesions. These eruptions usually began roughly ten days after the institution of the chemical into the wash-care program.

On two occasions we have specifically attributed the precipitation of extrinsic asthma in patients that have been symptom-free for many years. This came to my attention because one of the asthmatic patients is the daughter of my nurse, who made the observation simultaneously with the appearance of these unusual dermatoses in our clinial practice.

DONALD H. HULDIN, MD
Lansing, Mich

In Reply.—We appreciate the opportunity to place added perspective on the Letters to the Editor in this issue that refer to our Bounce fabric softener. We discussed the cases cited

in these letters with the physicians involved and have urged their participation in follow-up diagnostic patch or cautious reuse testing to determine whether there indeed exists a cause and effect relationship.

Bounce was heavily advertised during its marketing introduction, and free samples were distributed to a large percentage of US households. It has been our repeated experience that during such market introduction of any new product, some consumers and physicians will associate its use with personal problems that develop due to other causes. However, diagnoses from personal histories alone become much more difficult, because a high percentage of patients seen during this introductory period will report the new product as the only new item they have used.

Dr Hazelrigg stated in a telephone conversation that patch testing would be appropriate in the investigation of the dermatitides that he reported. However, he declined our suggestion that he test these patients, at our expense, to confirm his anecdotal observations. He also declined our encouragements to obtain diagnostic follow-up on the respiratory problems to which he referred.

Dr Sheard informed us that he has seen no problems that he attributes to the Bounce chemical ingredients. He believes that his patients have instead experienced a "mechanical" irritation from small pieces of fiber from the nonwoven rayon sheet that was used as the substrate for the fabric-softening agents. His patients were unavailable for controlled reuse testing that he agreed would be appropriate to determine if their dermatitides were actually related to this fabric softener. Dr Sheard, himself, experienced such a dermatitis. He has since reused Bounce with no recurrence of it. We have microscopically examined fabrics softened with Bounce in our laboratory, as well as softened clothing that a few consumers thought had caused their skin problems. No fibers from the rayon sheet were found.

Dr Huldin has also been contacted. He declined to consider any testing.

Since Procter & Gamble began selling Bounce four years ago, more than 40 million households have safely used over 2 billion sheets of it. Comments from consumers on the subject of its skin mildness have been consistent with those received for other safe products that we have marketed over the years. This is not at all surprising, since the ingredients in Bounce have been used safely for years in liquid fabric softeners or cosmetics.

Despite our confidence in Bounce's safety, we have followed up on every consumer complaint received. Whenever the consumers consented, we obtained the cooperation of local, independent physicians—primarily determatologists and allergists—in examining them and, when appropriate, in conducting patch tests with product ingredients and softened fabrics or prick tests with ingredients. The tests were performed at our expense to ensure the maximum cooperation of these patients. In none of the more than 350 completed, medically supervised tests has Bounce been shown to be the cause of dermatitides, respiratory distress, or other of the consumers' problems.

Examinations by local, independent dermatologists of about 90 additional consumers with active dermatitides showed a wide variety of actual causes. These include common topical and systemic bacterial or viral infections, scabies, jewelry allergy, and poison ivy. In about 100 other cases, consumers who had originally questioned Bounce's safety agreed to reuse it and are now using the product regularly without adverse effects.

The diagnostic testing experience with Bounce is consistent with extensive safety testing that was conducted earlier under well-defined, monitored protocols. Over 2,000 persons, including infants, participated in studies designed to assess skin safety. This testing consisted of patch tests for skin irritation, repeat insult patch tests for skin allergy, diagnostic testing for allergy among factory and laboratory workers who have had prolonged, intimate contact with the product and its ingredients, as well as clinical wear-testing of clothing and diapers that were softened with Bounce. Results from these tests demonstrate that Bounce is safe for consumer use. An independent panel of leading dermatologists who reviewed the safety data also concluded that Bounce was unlikely to cause dermatoses.

The net of the above remarks is that extensive safety testing and follow-up of consumer complaints have demonstrated that Bounce is a safe product for consumer use. We recognize that no testing program, however extensive, can anticipate the individual responsiveness of each of the 220 million persons in the United States. Nevertheless, diagnostic and laboratory testing experience indicates that even persons with atopic allergies have not responded unusually to this product.

We have voluntarily disclosed all of our safety information and consumer complaint files to the Bureau of Biomedical Science of the Consumer Product Safety Commission. They, too, have concluded, after careful study of all pertinent safety data, that Bounce is a nonhazardous consumer product.

It is appropriate to express appreciation to the vast majority of physicians who have responded to our request for assistance in obtaining definitive follow-up of problems that had been thought to be related to Bounce. Without their interest and cooperation, we would have been unable to conduct the thorough diagnostic program referred to previously. We continue to be interested in working with physicians who have patients who are candidates for diagnostic follow-up. Additional information and patch test materials for Bounce may be obtained by writing or telephoning me, collect, at area code (513) 977-3332.

Sunlight and Pityriasis Rosea

To the Editor.—Pityriasis rosea is a common self-limiting disease that affects children and young adults. Topical therapy has not been effective in promoting healing of the lesions or reducing the pruritus.[1] Ultraviolet light has been mentioned as helpful, but there is only one study substantiating such claims,[2] and the authors did not evaluate the effect on pruritus. This report describes one patient in whom lesions developed during the summer, when she had prolonged exposure to sunlight, and three others in whom the onset was in the fall when they were tanned but no longer exposed to sunlight. There was marked sparing of the tanned skin only in the patient who was exposed to the sun during the time the lesions were developing, suggesting a direct beneficial effect of light.

Report of Cases.—A 30-year-old woman complained of a nonpruritic eruption that had been spreading for several days. A single, asymptomatic, red, scaling lesion had been noted several weeks previously on the trunk. The patient had been in good health and denied taking any drugs. Findings of physical examination were unremarkable except for slightly elevated, round and oval, erythematous plaques, with a peripheral collarette of scale present primarily in the nontanned areas of the trunk. Complete blood cell count, urinalysis, Hinton test, and skin scrapings showed no abnormalities.

A 19-year-old woman, a 22-year-old woman, and a 30-year-old man all acquired the typical erythematous plaques of pityriasis rosea in the fall, when they were considerably tanned but no longer exposed to sunlight. There was no significant sparing of the tanned skin. Complete blood cell counts, urinalysis, Hinton test, and skin scrapings showed no abnormalities.

Comment.—The distribution of pityriasis rosea with the trunk being predominantly involved and the face and extremities spared might suggest that light has an ameliorating affect on the process. However, the scalp, palms, and soles, which are protected from the biological effects of light rarely show any lesions. If ultraviolet does suppress the disease, it appears that this happens only when the skin is exposed during the active phase. We have noted that in patients in whom pityriasis rosea develops in the fall, when they are no longer sunbathing but still retain their summer tan show no sparing of the sun-exposed skin of the trunk.

The mechanism by which ultraviolet light exerts its favorable effect is complex and may involve changes in the blood vessels, cells of the dermis, and the epidermis. Considering the renewed interest in ultraviolet light treatment[3] and the availability of improved light sources, further carefully controlled studies of pityriasis rosea using this form of therapy may be warranted.

Topical Therapy for Onychomycosis

To the Editor.—Chronic onychomycosis generally has required oral antifungal agents for therapy. The introduction of flucytosine for the treatment of systemic and topical fungal diseases has prompted the use of another fluorinated pyrimidine, fluorouracil (5FU), in the treatment of onychomycosis. Fluorouracil, in addition to being effective in the treatment of actinic keratoses, has also been shown to be effective for psoriasis of the nails (110:735, 1974).

Briefly, patients were entered into a double-blind study of a solution containing 1% fluorouracil in propylene glycol vs placebo solution (propylene glycol) with proved onychomycosis (as made evident by potassium hydroxide preparation and culture on Sabouraud agar). Three-week intervals were allowed between visits. Photographs were taken of the affected nails in addition to the laboratory tests. At the end of 12 weeks of therapy, a decision was made as to whether the patient had been receiving the "active" medication or the "placebo" medication as measured by the clinical response and laboratory results. If the patient was believed to be receiving "placebo" medication, then he/she was transferred to a single-blind phase of "active" medication, ie, the investigator knew the contents of the medication, but the patient did not.

In the ongoing study, 16 patients have completed 24 weeks of therapy and the code has been broken. The results have been as follows:

Nine patients initially received the "active" medication. In five, the condition cleared or markedly improved. One patient failed to respond to therapy even after being transferred at 12 weeks. Three patients were transferred at 12 weeks and began to respond to treatments late in the observation period.

Eight patients initially received placebo medication. Two showed clearing or marked improvement. Five patients were transferred at 12 weeks and improved on active therapy. One patient initially received placebo but was lost to follow-up after being transferred to active medication at 12 weeks.

Propylene glycol in high concentrations is a known antifungal agent; therefore, one might expect some success with the placebo alone. This did occur in two of eight patients. Five of eight patients responded to treatment with the active medication. The three patients originally receiving active drug began to respond late in the treatment period following transfer to second-phase active medication and presumably required a greater length of time to respond.

Topical therapy for onychomycosis achieving a 70% to 80% success rate would be an advance, since it is now difficult to achieve this rate with orally given antifungal agents. The study is still in progress, but I wish to share this information if it will aid any patient with onychomycosis who is unable to use oral antifungal agents for a medically valid reason.

FILLMORE K. BAGATELL, MD
Phoenix

Systemic Scleroderma in Mother and Daughter

To the Editor.—Systemic scleroderma still remains an uncommon disease of unknown cause, and the familial occurrence is very rare. We have seen two patients, a mother and a daughter in a family, with findings of systemic scleroderma.

Report of Cases.—CASE 1.—June 1975, a 45-year-old woman was admitted to the Hospital of the Hyogo College of Medicine with the chief complaint of hardening of her upper extremities. Fifteen years prior to admission, Raynaud phenomen of both hands and feet developed. She gradually noticed cutaneous hardness of her hands, forearms and feet, and then the shortness of her fingers and limitation of motion of her hands and fingers were recognized. Recently, she noticed slight retardation of the lips and loss of the ability to smile.

Laboratory Studies.—The erythrocyte sedimentation rate (ESR) was 103 mm/hr. The WBC count was 3,900/cu mm; the RBC count, 3.07×10^6/cu mm; the hematocrit reading, 25.0%; the hemoglobin concentration, 8.0 gm/100 ml; and the thrombocyte count, 4.3×10^4/cu mm. The serum globulin level was 7.4 gm/100 ml with an increased γ-globulin level. The immunoglobulin (IgG, IgA, and IgM) values were 3,600 mg/100 ml, 506 mg/100 ml, and 96 mg/100 ml, respectively. C-reactive protein was +1 positive, as was rheumatoid factor. The serum iron and copper values were 25 and 37 μg/100 ml, respectively. Normal data were obtained from urinalysis, serum electrolyte determination, lupus erythematosus (LE) test, anti-streptolysin O titer, and tests for liver and renal function. The serum antinuclear factor reaction and the test for syphilis were negative. A roentgenogram of the chest showed a bilateral

interstitial reticular pattern. A roentgenographic study of the upper part of the gastrointestinal tract showed the esophagus to be slightly atonic and dilated. The results of both the pulmonary function test and the ECG were in the normal range. The histocompatibility antigen (HL-A) typing examination showed A 9 and BW 40. The result of the chromosomal examination was normal.

The skin biopsy specimen from the forearm revealed a flattened epidermis, a collagenized, thickened dermis with minimal atrophy of the adnexa, homogenization, and hyaline changes. Masson stain showed an increased amount of collagen.

CASE 2.—A 27-year-old woman was examined at the Hospital of the Hyogo College of Medicine in June 1975. She was the eldest of the two daughters of patient 1. Consanguinity was not known in the family. It was believed that an onset of feeling of coldness of her both hands occurred when she was 14 years old. Since then, an increasing Raynaud phenomen of her hands and feet developed, along with progressive shiny stiffness of her hands and forearms and limitation of motion of small joints of hands and feet.

Laboratory Studies.—The following laboratory studies yielded normal values: urinalysis, complete blood cell count, serum electrolytes, C-reactive protein, rheumatoid factor, serum antinuclear factor, LE test, antistreptolysin O titer, and the VDRL test for syphilis. The ESR was 33 mm/hr. The serum globulin level was 8.1 gm/100 ml, with an increased γ-globulin level. The immunoglobulin (IgG, IgA, and IgM) determinations revealed 3,600 mg/100 ml, 506 mg/100 ml, and 548 mg/100 ml, respectively. Normal results were obtained from the ECG, tests for liver and renal function, pulmonary function, a roentgenogram of the chest, and a roentgenographic study of the upper part of the gastrointestinal tract. HL-A typing examination showed A 9, 10, and BW 40. No abnormalities were seen in the chromosomal analysis.

The skin biopsy specimen from the dorsum of the hand showed thickening and swelling of dermal collagen bundles. Masson stain showed an increased amount of collagen.

Comment.—Despite of the rarity of familial scleroderma, several cases of both systemic and localized scleroderma have been described.[1-5] Evidence such as a high level of antinuclear factor in the first-degree relatives[6] and significant results of HL-A typing,[7] suggest that genetic factors play a part in the etiology of systemic scleroderma. Burch and Rowell[8] proposed that the cause of systemic scleroderma was characterized by a single inherited dominant allele on the X-chromosome. However, the female predominance was not found in cases of the Brandywine isolate.[9] Though Emerit et al[10] found chromosomal abnormalities in lymphocyte mitoses of patients with scleroderma, our two cases were normal. The fact that there are several publications of familial scleroderma including these two cases, may encourage further search from the view of genetic predisposition to the disease.

Doxorubicin and Unusual Skin Manifestations

To the Editor.—Doxorubicin hydrochloride (Adriamycin), an anthracycline antibiotic that has a broad spectrum of antitumor activity, has been widely used as a single agent or in combination with other drugs.[1] The major toxic side effects have been nausea, vomiting, mucosal ulcerations, alopecia, hematopoietic depression, and cardiomyopathy. I would like to report two unusual melanotic cutaneous reactions related to doxorubicin therapy.

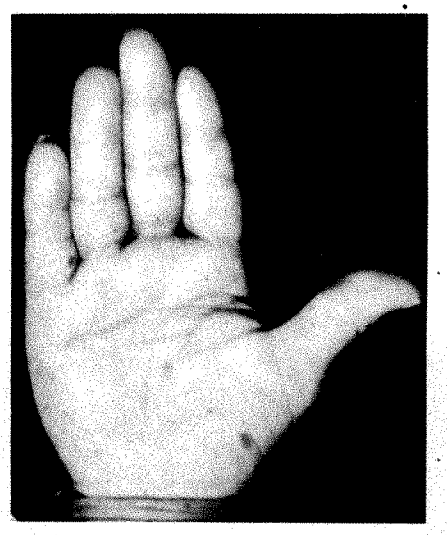

Fig 1.—Black hyperpigmentation on palm.

Fig 2.—Black hyperpigmentation on nails and nailbeds.

Report of Cases.—CASE 1.—A 55-year-old black woman was referred for chemotherapy for metastatic breast carcinoma. In November 1973, she underwent radical mastectomy for carcinoma of the left breast, with an uneventful recovery. In May 1974, an epidural metastasis developed, with compression of the spinal cord at the T-4 and T-5 levels. Laminectomy was performed and she was subsequently treated with cyclophosphamide (Cytoxan), methotrexate, vincristine sulfate, fluorouracil, and prednisone.[2] After further progression, with an appearance of new lesions in the spine, doxorubicin therapy was started. She was treated with a relatively low dose of 20 to 30 mg/sq m every three to four weeks. After a fifth course, or a total of 200 mg of doxorubicin, she noticed the black hyperpigmented changes in the palms, soles, nails and nail beds (Fig 1 and 2). However, the metastatic lesions responded to doxorubicin, and she received a total dose of 850 mg (400 mg/sq m). Subsequently, therapy was changed to vinblastine sulfate (Velban) and thiotepa. The skin changes improved when doxorubicin therapy was discontinued.

CASE 2.—A 51-year-old black woman was seen on Aug 27, 1975, for chemotherapy for

metastatic breast cancer. In 1951, the patient had had a hysterectomy and oophorectomy for uterine leiomyoma. In January 1975, she underwent left radical mastectomy for carcinoma of the breast. In August 1975, multiple pulmonary metastases developed and responded to cyclophosphamide, 100 mg/sq m orally from day 1 to 14; methotrexate, 40 mg/sq m intravenously on days 1 and 8; and fluorouracil, 500 mg/sq m intravenously on days 1 and 8 of the 28-day cycle. On Jan 21, 1976, a new lesion was observed in the left lung and doxorubicin therapy was started. After a second dose of doxorubicin, a total of 150 mg, she noticed hyperpigmented changes in the palms, dermal creases, and nail beds.

Comment.—The hypermelanotic pigmentary reaction as in these two patients had been recognized in children[3]; however, it has rarely been reported in adults.[4] Although the pathogenesis of this cutaneous manifestation is obscure, it appears to have a special predilection for the black race. There was no apparent correlation with the total dose administered and the development of the skin hyperpigmentation.

Primary Inoculation With *Mycobacterium marinum*

To the Editor.—Nontuberculous mycobacterioses are becoming more frequently recognized as etiological agents in cutaneous disease.[1-4] Recently we had the opportunity to observe the course of a cutaneous *Mycobacterium marinum* infection in an accidentally inoculated laboratory worker.

Report of a Case.—Late in the evening of Dec 31, 1973, while attempting to inject the tail vein of a mouse, a 21-year-old male research laboratory worker accidentally inoculated his left thumb with a needle on a syringe containing a viable suspension of a 4-week-old culture of *M marinum* W46 that was grown on Dubos Oleic Albumin medium. The culture was centrifuged, and the bacteria was resuspended in Hanks balanced salt solution, without adjuvant, to give approximately 3.7×10^6 colony forming units/ml. The site was cleansed with an antiseptic detergent containing hexachlorophene (pHisoHex), but no further therapy was initiated. Ten days later the area was erythematous and mildly tender. On Jan 15, 1974, a 1-mm pale-yellow papule surrounded by a 2-mm rim of erythema was observed. Smears of pus that were tested for acid-fast bacilli were positive. Cultures of the same material on Middlebrook 7H10 and Lowenstein-Jensen media that were incubated for two weeks at 32 C grew *M marinum*.

Susceptibility tests indicated the following: sensitive to streptomycin sulfate at 10.0 μg/ml; ethionamide, 5.0 μg/ml; kanamycin sulfate, 5.0 μg/ml; viomycin sulfate, 5.0 μg/ml; ethambutol, 5.0 μg/ml, rifampin, 1.0 μg/ml. Resistance was confirmed to isoniazid and PAS. One tuberculin unit of purified protein derivative that was injected intradermally resulted in 10 mm of induration within 48 hours. Roentgenograms of the thumb and chest were normal. The patient declined having a biopsy because he feared dissemination. Also, he did not wish local or systemic therapy because of potential adverse effects and anticipated spontaneous resolution.

By Feb 12, the lesion had increased in size to 6×8 mm and had become hyperkeratotic. Two weeks later two satellite lesions, which were 2×2 mm, were noted proximal to the nodule. By the end of July these satellite nodules had disappeared, and the lesion was showing resolution. Complete resolution with only a fine scar was noted 15 months after the initial inoculation. There has been no recurrence during the past two years.

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

SQUIBB® The Priceless Ingredient of every product is the honor and integrity of its maker. ™

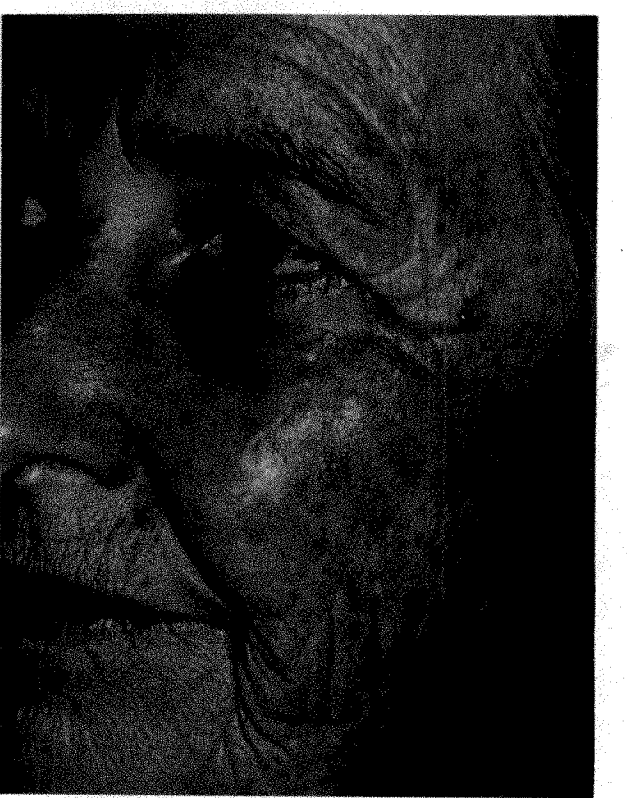
"Major improvement" in 5 days

Contact Dermatitis

Condition due to excessive use of 5-FU. Patient presented with intense pruritus, severe pain. Facial involvement sharply demarcated and acutely eczematous, erythematous and swollen—extending up into infra-orbital regions, but sparing eyelids and eyebrows.



After 5 days

Halog 0.1% cream applied twice daily. Pruritus and pain relieved within 48 hours. Examination on day 5 of therapy revealed major improvement with only mild, residual erythema still present. Total resolution of all lesions nine days later, at which time therapy was discontinued.

Case history on file at Squibb Institute for Medical Research.

Dermatophilus Infection in Animals and Man

Edited by
D. H. LLOYD and K. C. SELLERS

This book is the proceedings of a symposium on Dermatophilus infection held at the University of Ibadan, Nigeria, which brought together research workers interested in the disease from various parts of the world, and provided a forum for discussion of the many controversial aspects of the subject.

The book includes chapters on the prevalence and epidemiology of Dermatophilus infection in tropical, subtropical and temperate regions of the world. There are sections on the pathology, bacteriology and immunology of the disease, its economic effects and methods for its prevention and control—in particular the use of a recently developed method of prophylactic vaccination is described. A chapter is specifically devoted to a review of the disease in man and other primates, and the final section of the book deals with controversy over the classification of *Dermatophilus congolensis* and the nomenclature of different clinical forms of Dermatophilus infection.

CONTENTS: The Epidemiology of Dermatophilus Infection: The Disease in Africa; The Disease in Europe and the Middle East; The Disease in America; The Disease in Primates; The Analysis of Epidemiological Information. The Site of Infection by *Dermatophilus congolensis*: The Pathology of Dermatophilus Infection. The Bacteriology of *Dermatophilus congolensis*. The Immunology of Dermatophilus Infection. The Treatment and Control of Dermatophilus Infection. The Economic Consequences of Dermatophilus Infection. Nomenclature in Dermatophilus Infection: A Discussion.

FULVICIN-U/F® Tablets brand of griseofulvin (microsize) tablets, U.S.P.
CLINICAL CONSIDERATIONS—
INDICATIONS Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), *Tinea versicolor*, Nocardiosis.
CONTRAINDICATIONS This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.
WARNINGS **Prophylactic usage:** Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established.
Animal toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in pregnancy: The safety of this drug during pregnancy has not been established.
Animal reproduction studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
PRECAUTIONS Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system functions, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
ADVERSE REACTIONS When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate counter-measures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if graulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
AVAILABLE in 125 mg., 250 mg., and 500 mg. scored tablets.
010 AUGUST 1973

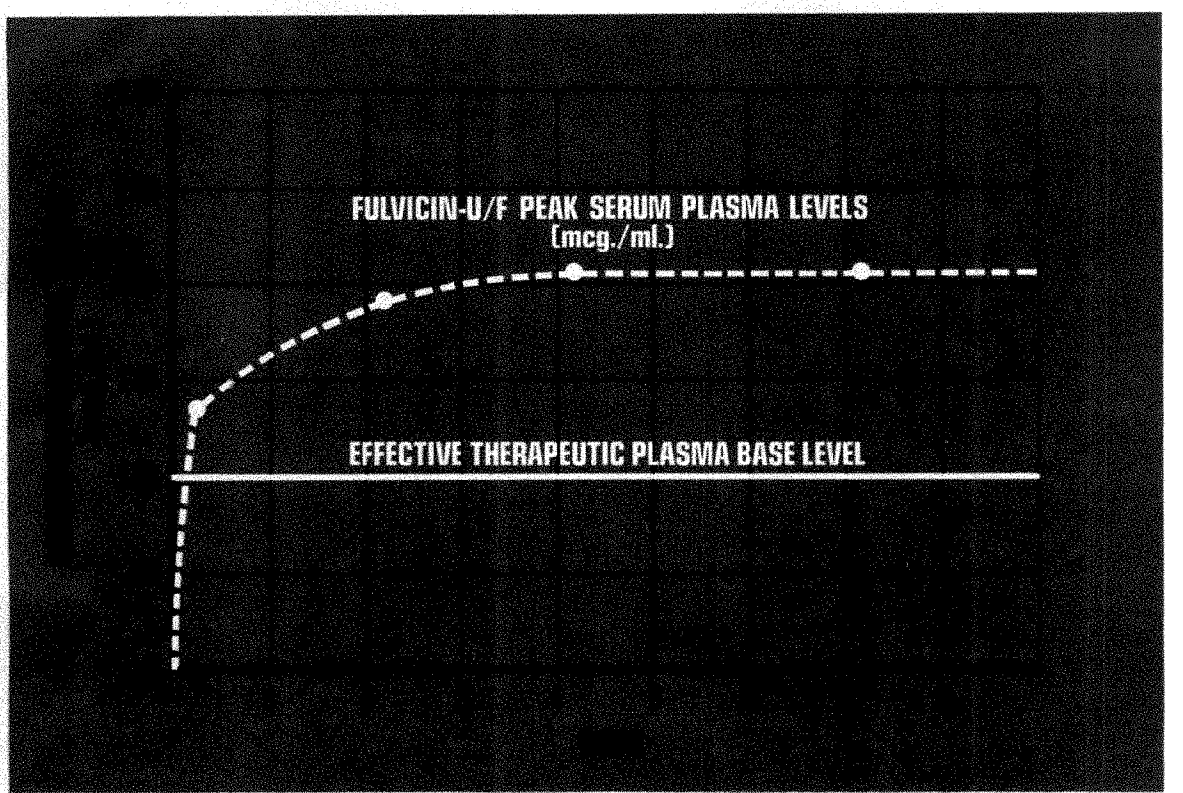
SUSTAINED THERAPEUTIC PLASMA LEVELS WITH ONLY ONE TABLET A DAY

Schering



Adapted from Symchowicz, S., and Katchen, B.: J. Pharm. Sci. 57:1383, 1968.

The above graph depicts average peak serum plasma levels of FULVICIN-U/F following once-daily dosage of one FULVICIN-U/F 500 mg. tablet given before breakfast to six normal subjects for a seven-day period.

Hours of fungistatic action at ringworm sites

The above graph on plasma levels of FULVICIN-U/F 500 mg. in once-daily dosage indicates that this dosage is adequate to keep the antibiotic available for antifungal action in the keratin precursor cells where fungi have invaded. With the growth checked by the fungistatic action, the fungi are cast off as the keratin grows out and sloughs off. Healthy tissue replaces infected keratin of skin, hair, and nails.

Clinical efficacy, safety, and convenience

The Ultra-Fine form of FULVICIN®—in clinical use for over 15 years—possesses two vital keys to success in long-term ringworm therapy: product familiarity, and the confidence that comes after years of effective and safe therapy. For your patient: dosage simplicity. The easy-to-remember, once-a-day routine that helps avoid dosage delinquency and the possibility of therapeutic setbacks when therapeutic plasma levels are not maintained.

Marian M. Brubaker, MD, Recorder

Prurigo Nodularis, Presenting as a Pseudotumor. Presented by DON E. SUTER, MD, ALFRED TROSOW, MD.

A 48-year-old man was seen initially in April 1975 with a 2.5-cm firm tumor of the right temple that had an oozing surface and that had been present for three weeks. There were no cervical nodes. He has a history of recurrent, long-term pruritic eruptions of his arms and trunk attended with scratching. There is a 20-year history of ulcer symptoms, for which he takes antacids. He bathes frequently and has used various antibacterial soaps.

Results of a complete blood cell count, VDRL test for syphilis, and urinalysis and chest film were all normal. Biopsy specimens were taken from the left temple lesion and from a lesion on the left side of the chest. These specimens were examined by Dr Elson B. Helwig of the Armed Forces Institute of Pathology and were diagnosed as chronic dermatitis. Because of the marked acanthosis, the diagnosis of prurigo nodularis was suggested by one member of the staff.

Treatment has consisted of 0.1% betamethasone (Valisone) cream, which cleared most of the trunk and arm lesions, but made little change in the temple lesion.

Discussion

DR LEO INDIANER: I could only interpret the slide as pseudoepitheliomatous hyperplasia. This is not my concept of prurigo nodularis. It would be nice to postulate that this is caused by neurodermatitis and that it is a pseudotumor. It is a tumor only clinically; it still may be a tumor histologically if other areas are examined.

DR SAMUEL AYRES JR: I cannot go along with the diagnosis of prurigo nodularis. The patient said he had had an itchy eruption from the age of 4 to 18, but for the ensuing 30 years, he had no skin trouble until two months ago. Now he has this single lesion. I do not see how you can connect this with prurigo nodularis. I do not know what the lesion is. It looks like some type of granuloma. A suberythema dose of x-ray therapy might be of some benefit.

DR LAWRENCE NELSON: Occasionally, we see this solitary-type lesion in patients in mental institutions. They will chew an arm and get a similar lesion, but with hair growing in the site.

DR LYON ROWE: Clinically, prurigo nodularis should be single or multiple hard keratotic nodules that the patient manipulates. Also, the microscopic sections have been described as having fragmented nerve fibers imbedded in the lesions. Thus, neither clinically nor histopathologically does this case fit prurigo nodularis.

DR SUTER: Dr Trosow disagrees with prurigo nodularis. I do not. A patient with prurigo nodularis picks at his skin chronically, as this man does. He had 15 or 20 lesions on his trunk when we saw him three weeks ago. They have markedly subsided, but they are still palpable. He scratches. My impression when I first saw him was that he had a metastatic or primary carcinoma on his temple. I think that this is a localized hypertrophic neurodermatitis or something similar, and that this is what prurigo nodularis is. It remains to be proved whether or not the histopathologic features are as exact for this disease as now stated.

Lepromatous Leprosy. Presented by RONALD REISNER, MD, SUSAN PHELPS, MD.

The patient is a 21-year-old woman (eight months pregnant) from Guadalajara, Mexico, who has been living in California for the past three years. She visits Mexico each year. During the last seven months, she has noted a pruritic macular scaling eruption on her extremities. In the last three months, she has developed tender nodules on her extremities, with some numbness of her toes. There are no other systemic complaints. She denies that any other family member has had a similar eruption.

On examination, there is a purplish reticulated pattern on her extremities, with scattered and slightly tender nodules primarily on the legs, with a few lesions on the forearms. The ulnar nerves are slightly palpable. There is no loss of eyebrows.

A complete blood cell count was done. The hemoglobin value was 11.3 gm/100 ml; the hematocrit reading was 34.7%; and the WBC count was 6,400/cu mm, with a normal differential cell count. The platelets were adequate, and the ESR was 38 mm/hr. Results of blood chemistry studies with an automated analysis system and blood creatinine level were normal. The VDRL test for syphilis was negative. The biopsy diagnosis was leprosy, with a positive Fite stain.

Discussion

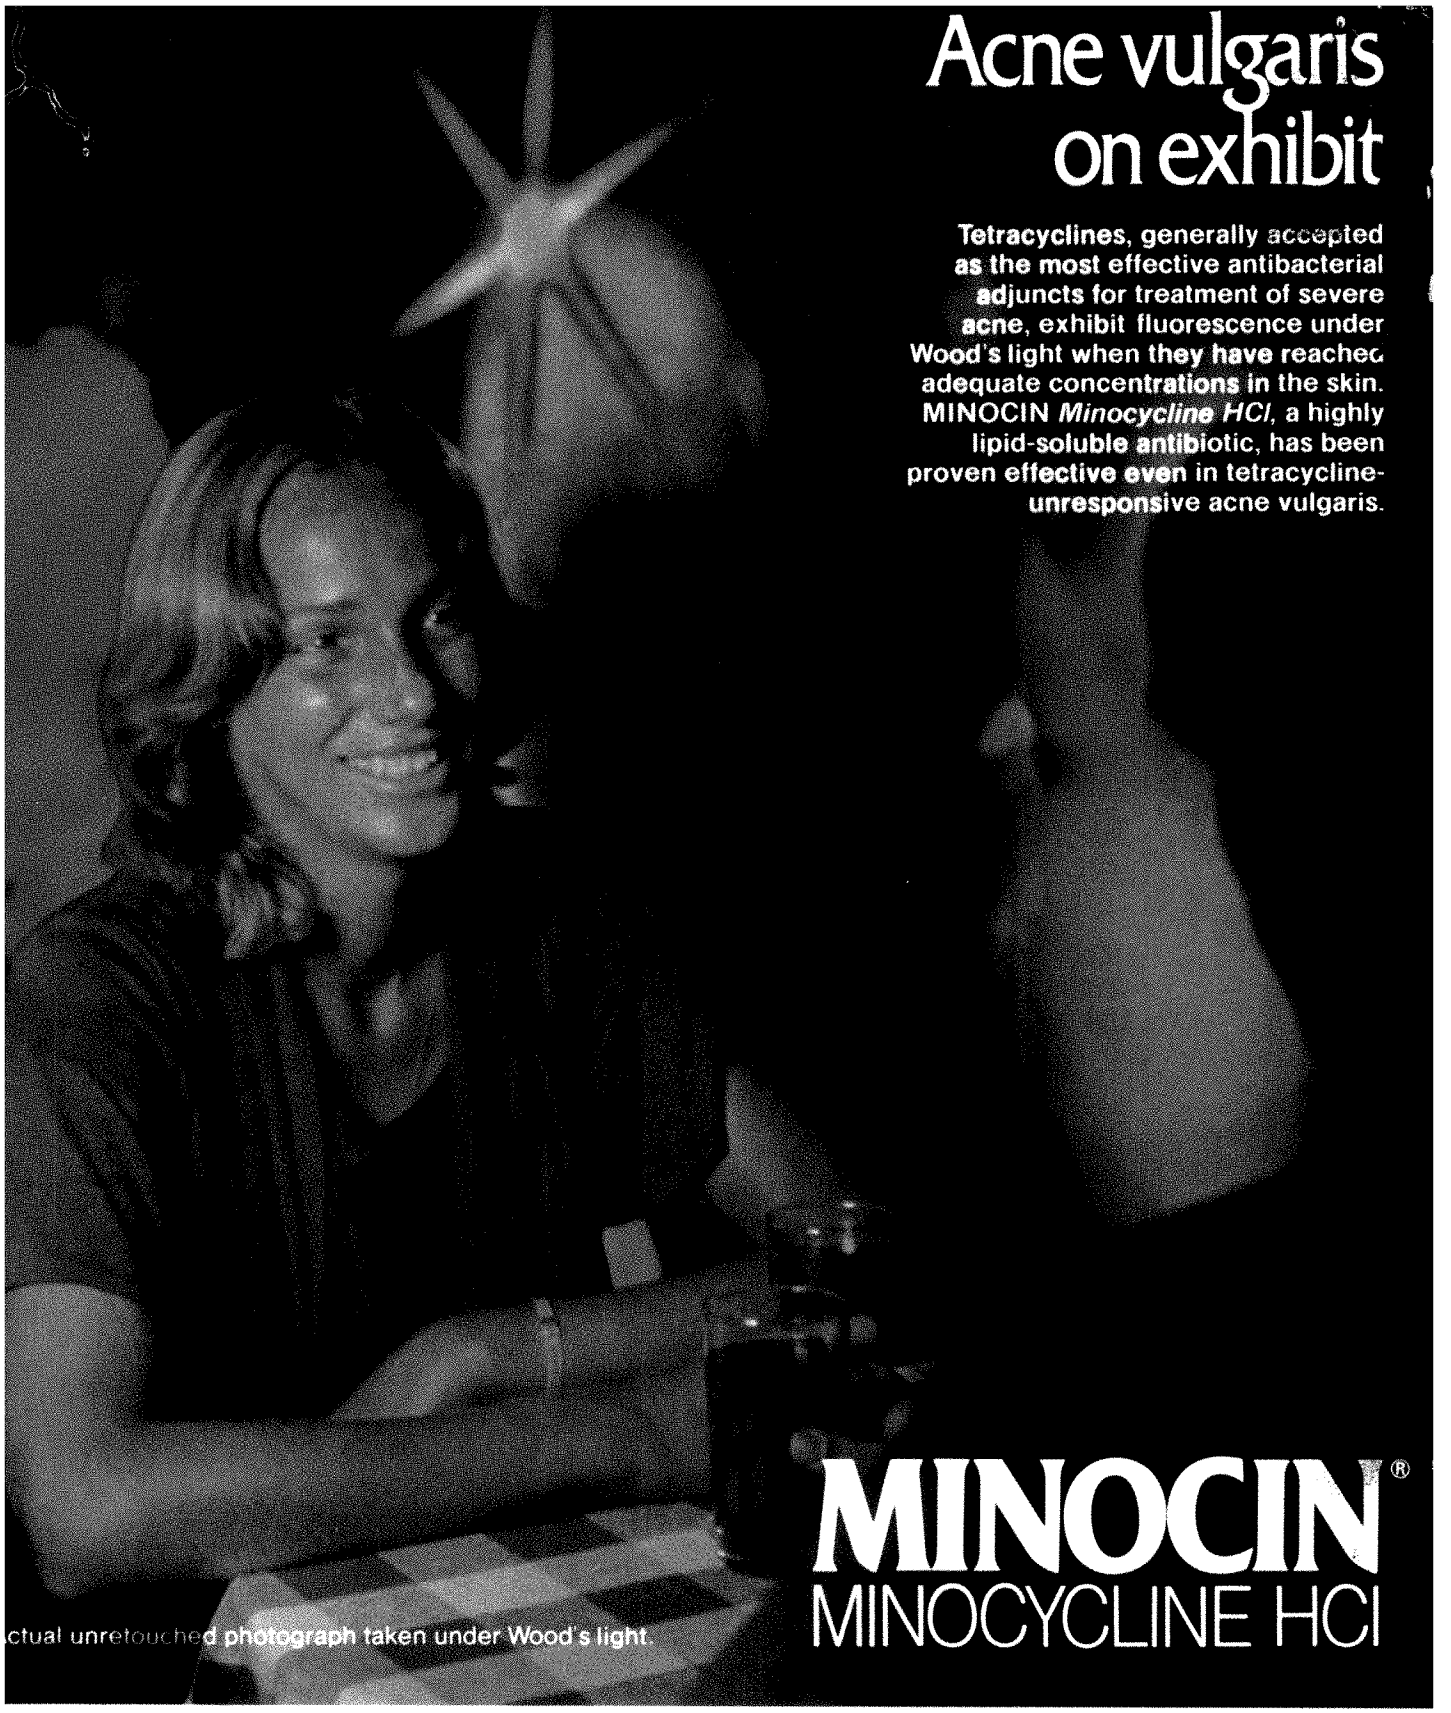
DR CARL KORN: This is a case of lepromatous leprosy of the diffuse form that shows evidence of nodular formation. The focus here is on an immediate therapeutic decision: the form of therapy to choose and whether treatment should be instituted immediately in leprosy newly diagnosed in a woman eight months pregnant, or be delayed until after delivery. The objectives include control of the disease in the patient and reduction of the risk of transmission to others. The unusual features of this case concern the possibility of fetal transmission and the fact that the patient was in a reactional state when first examined, having erythema nodosum leprosum (ENL).

The standard therapeutic agent in leprosy remains the sulfones. Their effect is slow, as measured by both the clinical course and by the available methods for determining their bacteriostatic action. These methods include the bacteriologic index and the morphologic index, which have been extrapolated to apply to transmissibility of the disease; but their relevance is highly inferential. There is much that is certain regarding transmission of the disease. Intrauterine transmission is not known to occur. Household exposure of young children and others can result in infection. The Kluth study in Texas several years ago showed 4% of the offspring living with parents who had active lepromatous leprosy developing the disease.

Our experience has been that leprosy is not transmitted across the placental barrier. Also, transmission to contactants of treated cases is rare. In southern California, leprosy is essentially an imported disease. In view of this, there is no reason to institute therapy to protect the fetus.

One might consider the possibility that the earlier treatment is begun in the mother, the less the risk of postpartum transmission to the infant. However, the slow effect of the sulfones indicates there would be no harm in delaying sulfone therapy a month now, and there may be advantages to this short delay. Since the patient is in a reactional state of ENL, and evidence is that this can occur in the absence of or prior to any sulfone therapy, it may be potentiated by sulfones. With the advent of thalidomide, this has not been a problem when the drug can be used in lepromatous leprosy. However, can we use thalidomide during pregnancy? Our evidence concerning embryopathy is that it occurs with the administration of the drug early in pregnancy. Nevertheless, I would advise erring on the side of caution; it would be difficult to defend thalidomide's use should a malformed fetus be delivered.

Other factors we may consider in this patient have to do with isolation, childhood leprosy, and sulfone-induced anemia. It is no longer standard practice to isolate patients, even those with lepromatous leprosy. It certainly is not the practice to separate a mother and her child. With regard to childhood leprosy, many children possibly have a limited form of the disease and heal spontaneously. Finally, an almost constant side effect of sulfone therapy is a shortened RBC half-life and resultant anemia. Fortunately this anemia is generally mild, limited to a 2.0- to 4.0-gm drop in the hemoglobin level; but, this may be important in pregnancy. In summation, I would withhold sulfone therapy in this pregnant woman until after delivery of her baby.



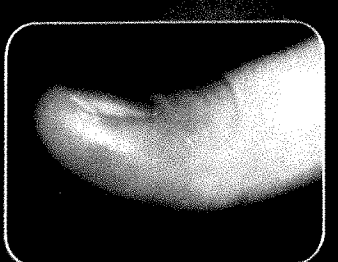
INOCIN Minocycline HCl
ral and Intravenous Brief Summary
ontraindications: Hypersensitivity to any tetracycline.
arnings: Intravenous use, particularly in pregnancy, in daily oses exceeding 2 grams has been associated with deaths rough liver failure. When need for intensive treatment outeighs potential dangers, perform renal and liver function tests efore and during therapy; also follow serum concentrations. In nal impairment, usual doses may lead to excessive accumulaon and liver toxicity. Under such conditions, use lower total oses, and, in prolonged therapy, determine serum levels. This azard is of particular importance in I.V. use in pregnant or ostpartum patients with pyelonephritis. In such cases, the blood vel should not exceed 15 mcgm/ml, and liver function tests ould be made at frequent intervals. Do not prescribe other

cyclines during tooth development (last half of pregnancy, infancy and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies to date indicate that photosensitivity is rarely reported with MINOCIN *Minocycline HCl*. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an

acidosis. CNS side effects (lightheadedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. **Newborns, infants and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg /kg every 6 hours, demonstrated a decrease in fibula growth rate, reversible when drug was discontinued. Tetracyclines are present in the milk of lactating women who are taking a drug in this class.

Staph infection: Skin deeper

When the patient is penicillin-hypersensitive, when bacteriologic testing shows *Staph. aureus* to be resistant or the infection has proved unresponsive, MINOCIN *Minocycline HCl* may be an effective alternative.* Clinical studies have demonstrated satisfactory response in 156 of 173 simple or mixed skin and soft tissue infections due to staphylococci.



Actual patient photograph after 7 days of MINOCIN.

MINOCIN®
MINOCYCLINE HCl

CAPSULES 50 mg and 100 mg
SYRUP 50 mg/5 cc
INTRAVENOUS 100 mg/vial

100 or 200 mg initially, 50 mg *q.i.d.* or 200 mg initially, 100 mg *b.i.d.*

*Tetracyclines are not the drugs of choice in the treatment of any type of staphylococcal infection. MINOCIN is indicated for treatment of *Staphylococcus aureus* skin and soft tissue infections only when bacteriologic tests indicate appropriate susceptibility to the drug.

MINOCIN Minocycline HCl
Oral and Intravenous Brief Summary (continued)
organisms, including fungi. If superinfection occurs, institute appropriate therapy. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (*e.g.*, renal, hepatic and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.
Adverse Reactions: GI: (with both oral and parenteral use) anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital dermatitis (uncommon). Photosensitivity is discussed above ("Warnings"). **Renal toxicity:** rise in BUN, dose-related (see "Warnings"). **Hypersensitivity reactions:** urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (see "Warnings"). When given in high doses, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur. **NOTE: Concomitant therapy:** Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral minocycline. Studies to date indicate that absorption of MINOCIN *Minocycline HCl* is not notably influenced by foods and dairy products.

CNS side effects including lightheadedness, dizziness, or vertigo have been reported with MINOCIN. Patients who experience these symptoms should be cautioned about driving vehicles or using hazardous machinery while on minocycline therapy.

...allergic dermatoses

with strong emotional overlay

Atarax®

(hydroxyzine hydrochloride)

TABLETS: 10 mg, 25 mg, and 50 mg

- rapid antianxiety action
- demonstrated antihistaminic activity

Contraindications: Hypersensitivity to hydroxyzine. Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

ROERIG Pfizer

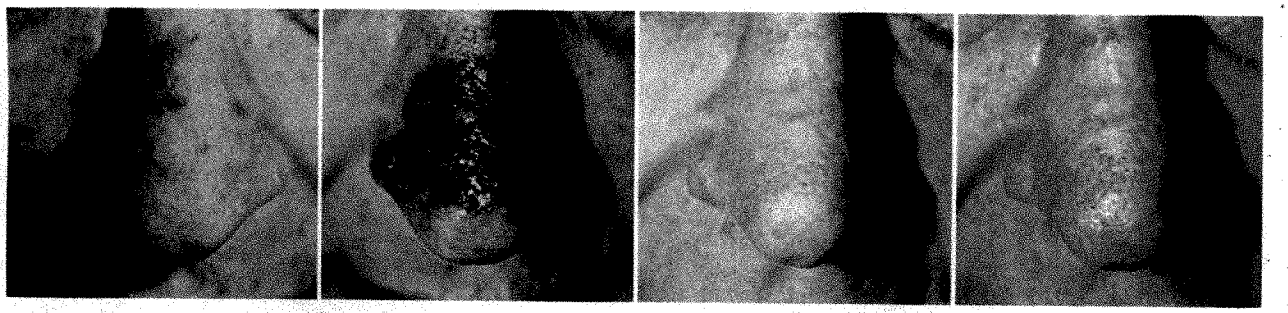
ROCHE

Roche Laboratories announces an additional therapeutic application for Efudex® 5% Cream fluorouracil/Roche

now indicated for superficial basal cell carcinoma



8/8/69
Before treatment a superficial, scaly, slightly excoriated lesion was present. Biopsy revealed the lesion to be a superficial basal cell carcinoma.

9/25/69
After 7 weeks of treatment with Efudex (fluorouracil) 5% Cream, lesion site is clearly delineated, markedly erythematous; surrounding skin shows no reaction to medication. Treatment terminated.

12/10/70
Follow-up approximately 14 months after treatment; healing has occurred with minimal scarring.

4/18/74
Patient has been followed continuously since treatment. **No evidence of recurrence.**

Efudex (fluorouracil) 5% Cream is recommended as an effective topical alternative to surgery for multiple lesions and difficult treatment sites.

A proven cytotoxic agent that exerts a marked effect on cells that grow more rapidly.

Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity. Normal tissue rarely affected. Convenient, economical b.i.d. application.

Prolonged exposure to ultraviolet light may accelerate reaction to medication. If an occlusive dressing is used, there may be an increase in the incidence of inflammatory reactions in the adjacent normal skin.

An exclusive Roche formulation

Efudex® 5% Cream

fluorouracil/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).
Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.
Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.
Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.
Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity **(only 5% strength recommended)** to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.
How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

Proven
Psoriatic Therapy for
24-hour Coverage
24-hour Psoriatic Therapy

estar™

Therapeutic Tar Gel

Tar odor won't betray **estar** therapy. Proven **estar** Therapeutic Tar Gel is equivalent to 5% crude coal tar in everything but odor. No sticky, greasy residue to remain on the skin . . . proven therapy to control the formation of psoriatic scales and reduce itching with antipruritic action so that scratching is less likely.

The gel base enables the patient to apply **estar** evenly and smoothly. Tar therapy that doesn't smell like it . . . **estar** Therapeutic Tar Gel.

Balnetar®

Water-dispersible Emollient Tar

Change ordinary water into a psoriatic treatment for patients who bathe before bedtime. **Balnetar** can work through the night to provide keratoplastic, antieczematous, and antipruritic action. It lubricates and moisturizes the skin to relieve and help prevent excessive dryness while it softens and aids in the removal of scales and crusts. One to three capfuls of **Balnetar** added to a tub of warm water can extend the effect of **estar** Therapeutic Tar Gel to twenty-four hour tar therapy. The active ingredient in **Balnetar** treats the skin without staining it or the porcelain of the tub.

Sebutone®

Therapeutic Tar Shampoo

When psoriasis finds its way to the scalp, **Sebutone** can penetrate, soften, and remove scales, crusts, and excess oil with its chemically and biologically standarized tar. Microfine particles of tar remain on the scalp for up to three days (as shown with Wood's light) providing prolonged residual action. The fresh, clean fragrance and excellent cleansing properties of **Sebutone** make no other shampoo necessary when treating scalp psoriasis or any stubborn case of seborrhea or dandruff.

estar™

Therapeutic Tar Gel

Composition: Westwood® Tar (biologically equivalent to 5% Coal Tar USP) in hydro-alcoholic gel (29% alcohol).

Actions and Uses: A therapeutic aid in the treatment of psoriasis and other tar responsive dermatoses such as eczema (atopic dermatitis, lichen simplex chronicus, nummular eczema) and seborrheic dermatitis. **estar** is suitable for use in a modified Goeckerman regimen, either in the hospital or on an outpatient basis; it also can be used in follow-up treatment to help maintain remissions.

Contraindications: estar should not be applied to acutely inflamed skin or used by individuals who are known to be sensitive to coal tar.

Dosage and Administration:

Psoriasis:
The patient should massage **estar** into affected areas, once or twice per day or as directed by physician. Rub in well, allow the gel to remain for five minutes, and then remove excess by patting with tissues.

Chronic atopic dermatitis, Lichen simplex chronicus, Nummular eczema, and Seborrheic dermatitis:

One or two applications per day, as described above, are suggested. If dryness occurs, an emollient may be applied one hour after **estar.**

Caution: AFTER USING, PROTECT TREATED AREAS FROM SUNLIGHT UNLESS DIRECTED BY PHYSICIAN. DO NOT USE ON HIGHLY INFLAMED OR BROKEN SKIN. If used on the scalp, temporary discoloration of blond, bleached or tinted hair may occur. If undue irritation develops or increases, discontinue use and consult physician. AVOID CONTACT WITH EYES. In case of contact, flush eyes with water.

Slight staining of clothing may occur. Standard laundry procedures will usually remove stains.

For complete prescribing information, see PDR.

SUPPLIED: 3 oz. plastic tube.

Balnetar®

Water-dispersible Emollient Tar

CONTAINS: WESTWOOD® TAR (Equivalent to 2.5% crude coal tar U.S.P.) mineral oil, and lanolin oil.

Balnetar is an important adjunct in the management of a wide range of dermatoses, including:

Atopic dermatitis
Psoriasis
Chronic eczematoid dermatitis
Eczematoid dermatitis
Seborrheic dermatitis

Suggested for use in modified Goeckerman regimen.

Directions:
Balnetar should always be used with water—either added to water or rubbed into wet skin.

Bath: Add 1 to 3 capfuls to a tub of warm water. Do not use soap. Soak for 10 to 20 minutes. Pat dry. Frequency depends on nature and severity of condition.

Direct Application: Pat off excess with tissue or old towel to help minimize staining of clothing or linens.

Scalp Application: Mix 2 to 3 capfuls with ¼ cup of water. Rub into scalp with fingertips. Apply once a day, preferably before bedtime. A therapeutic shampoo may be used the following morning.

Contraindication: Not indicated when acute inflammation is present.

CAUTION: If irritation persists, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. In rare cases, Balnetar may cause allergic irritations attributable to coal tar. Keep out of the reach of children. AVOID CONTACT WITH EYES.

PRECAUTION: After use of Balnetar, avoid exposure to sunlight unless otherwise directed by physician. GUARD AGAINST SLIPPING IN BATHTUB. TO AVOID STAINING, DO NOT USE IN FIBER GLASS BATHTUBS.

SUPPLIED: 8 fl. oz. plastic bottles.

Sebutone®

Therapeutic Tar Shampoo

CONTAINS: WESTWOOD® TAR (equivalent to 0.5% Coal Tar U.S.P.) sulfur 2% and salicylic acid 2% in SEBULYTIC® brand of unique penetrating surface-active combination of soapless cleaners and wetting agents.

CAUTION: If undue skin irritation develops or increases, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. For external use only. Keep out of the reach of children. AVOID CONTACT WITH EYES. IN CASE OF CONTACT, FLUSH EYES WITH WATER.

SUPPLIED: 4 and 8 oz. bottles and Sebutone Cream in 4 oz. tubes.

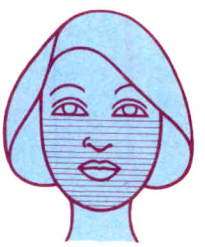
Four indications for Komed® HC Acne Lotion

Komed HC reduces inflammation as it keeps skin dry and desquamating with non-comedogenic sodium thiosulfate[1]

1.

When you wish to alternate severe acne medication with acne medication that will reduce erythema and irritation

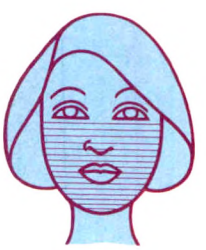


3.

When you determine that initial use of severe acne medication is not indicated

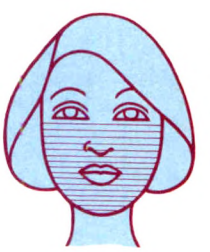
2.

When severe acne medication has been effective and you want to maintain acne control with minimal irritation



4.

When reducing the inflammation associated with acne vulgaris is an important consideration



Besides its ability to reduce inflammation, patients appreciate the invisibility of Komed HC. It dries rapidly to a transparent film to be worn unseen or used as the base for makeup.

Contraindications Contraindicated for herpes simplex, chickenpox, smallpox, tuberculous ulcers and fungal infections.
Warning Although there have been no reports of topical stercids having adverse effects on pregnant patients, the safety of their use has not been established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time during pregnancy.
For acne conditions not requiring the anti-inflammatory effects of hydrocortisone, KOMED lotion or KOMED MILD lotion are recommended.
Precautions If signs of irritation or sensitivity develop, discontinue use. If infections due to bacteria or fungi appear during therapy, appropriate measures should be taken. The anti-inflammatory action of hydrocortisone may mask the presence of infection. Do not use on or about the eyes.
Caution U S. Federal law prohibits dispensing without a prescription.

The cosmetically acceptable infection fighter

NEOSPORIN®G Cream

(polymyxin B-neomycin-gramicidin)

Each gram contains Aerosporin® brand Polymyxin B Sulfate 10,000 units; neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); gramicidin 0.25 mg. Inactive ingredients: liquid petrolatum, white petrolatum, purified water, propylene glycol, polyoxyethylene polyoxypropylene compound, emulsifying wax, and 0.25% methylparaben as preservative.

NEOSPORIN®G Cream
(polymyxin B-neomycin-gramicidin)

When topical infection invades hairy areas, facial skin or intertriginous areas, Neosporin®-G Cream provides broad antibacterial coverage. It contains three antibiotics that combat virtually all pathogenic bacteria found topically.*

These antibiotics are seldom used systemically, so the patient is spared the possibility of sensitization to those antibiotics which might later be required systemically.

Smooth vanishing cream base leaves no greasy residue on skin, no stains on fabric.

Wellcome / **Burroughs Wellcome Co.**
Research Triangle Park
North Carolina 27709

*INDICATIONS: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: For topical administration for the treatment of the listed localized infections or for suppressive therapy in such conditions: · primary pyodermas (impetigo, ecthyma, sycosis vulgaris, paronychia) · secondary infected dermatoses (eczema, herpes, and seborrheic dermatitis) · traumatic lesions (inflamed or suppurating as a result of bacterial infection).

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: Not for use in the eyes or in the external ear canal if the eardrum is perforated. This product is contraindicated in those individuals who have shown hypersensitivity to any of its components.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, such as chronic otitis externa or stasis dermatitis, it should be borne in mind that the skin in these conditions is more liable than is normal skin to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

HOW SUPPLIED: Tube of 15 g.

UNIVERSITY OF MEDICINE LIBRARY C. U.

Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

Get down to the level of normal skin.

Remove hyperkeratotic build up safely and effectively.

Keralyt® Gel is clear, and easy to apply. Keralyt Gel's mechanism of action is believed to be its ability to dissolve the intracellular material that binds the cells of the stratum corneum, thus aiding the simple, safe removal of excessive hyperkeratotic skin.

Keralyt's keratolytic action is an important preliminary to other topical agents. After the hyperkeratotic barrier is removed, tar, steroids, and other therapy can function with less impediment.

Keralyt® GEL

6% salicylic acid in a gel containing propylene glycol (60%), ethyl alcohol (19.4%), hydroxypropyl cellulose and water.
Please see full prescribing information.

©1977, W.P. Inc.

Available only on your prescription.

Keralyt® GEL

NDC-0072-6500-01

Rx CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

CONTENTS: 6% salicylic acid in a gel containing propylene glycol (60%), ethyl alcohol (19.4%), hydroxypropyl cellulose and water.

ACTION AND USES:
For Dermatological Use: Keralyt is a topical aid in the removal of excessive keratin in hyperkeratotic skin disorders, including the various ichthyoses (vulgaris, sex-linked and lamellar), keratosis palmaris and plantaris, keratosis pilaris, pityriasis rubra pilaris, psoriasis (including body, scalp, and palms and soles). Keralyt has been reported as helpful as adjunctive therapy for fungal infections.

For Podiatric Use: Keralyt is a topical aid in the removal of excessive keratin in dorsal and plantar hyperkeratotic lesions. Keralyt has been reported as helpful as adjunctive therapy for verruca plantaris.

DIRECTIONS FOR USE: The preferable method of use is to apply thoroughly to the affected area and place under occlusion at night. The skin should be hydrated for at least five minutes prior to application. The medication is washed off in the morning, and if excessive drying and/or irritation is observed, a bland cream or lotion may be applied. Once clearing is apparent, the occasional use of Keralyt will usually maintain the remission. In those areas where occlusion is difficult or impossible, application may be made more frequently, and hydration by wet packs or baths prior to application apparently enhances the effect. Unless hands are being treated, rinse hands thoroughly following application.

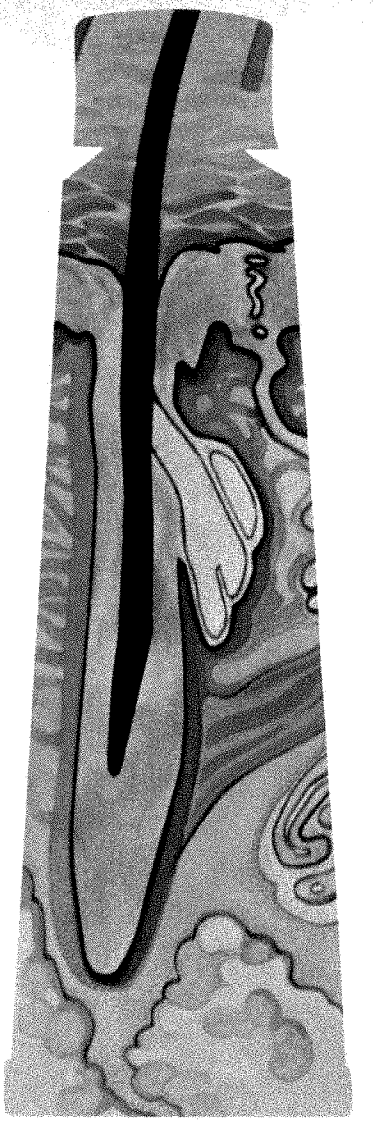
CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Keralyt.

PRECAUTIONS: In view of the salicylic acid content, use in children under 12 years of age should be limited to no more than one tube (1 oz.) in 24 hours. Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medications out of reach of children.

HOW SUPPLIED: Plastic tubes 1 oz. (24.8 gm.)

WESTWOOD PHARMACEUTICALS INC.
Buffalo, New York 14213

a new potency to provide a different set of benefits



a strength to consider... for treating large skin areas and for use with occlusive dressings

More to it

INDICATIONS: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.
CONTRAINDICATIONS: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.
WARNINGS: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.
PRECAUTIONS: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions. *ARISTOCORT A Spray Lotion only:* Take care when using periorbitally, or in the scrotal, vulvar or perineal areas due to a fairly high incidence of burning sensation.
ADVERSE REACTIONS: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.
SUPPLIED: *Cream 0.5%* — Per Gm.: triamcinolone acetonide 5 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.1%* — Per Gm.: triamcinolone acetonide 1 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.025%* — Per Gm.: triamcinolone acetonide 0.25 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; all potencies are in a water base of mono and diglycerides, squalane, polysorbate 80 USP, polysorbate 60, synthetic spermaceti NF, stearyl alcohol USP, Tenox II, and sorbitol solution USP. *Ointment 0.5%* — Per Gm.: triamcinolone acetonide 5 mg.; inactive ingredient: white petrolatum; *Ointment 0.1%* — Per Gm.: triamcinolone acetonide 1 mg.; inactive ingredient: white petrolatum. *ARISTOGEL® Gel 0.1%* — Per Gm.: triamcinolone acetonide 1 mg., 1.8% benzyl alcohol as preservative; inactive ingredients in a water base: polysorbate 80 USP, polyoxyethylene (20) cetyl ether, glycerin USP, and citric acid USP.
ARISTOCORT A CREAM: Each gram of ARISTOCORT A contains 0.25 mg. (0.025%), 1 mg. (0.1%), or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in AQUATAIN, a specially formulated base composed of emulsified wax NF, isopropyl palmitate, glycerin USP, sorbitol solution USP, lactic acid, 2% benzyl alcohol and purified water. AQUATAIN is non-staining, water-washable, paraben-free, spermaceti-free and has a light texture and consistency.
ARISTOCORT A OINTMENT: Each gram of ARISTOCORT A Ointment contains 1 mg. (0.1%) or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in a specially formulated base composed of emulsifying wax NF, white petrolatum, and propylene glycol. In addition, the 0.1% Ointment contains Tenox II and lactic acid.
ARISTOCORT A SPRAY LOTION: Each 15 Gm. pressurized aluminum can contains 2.94 Gm. of a concentrate supplying a minimum of 17 mg. of ARISTOCORT A triamcinolone acetonide; inactive ingredients: alcohol 18.1% and isopropyl myristate; propellants: dichlorodifluoromethane and cryofluorane.

Vanoxide® Acne Lotion and Loroxide® Acne Lotion

Description: Vanoxide Acne Lotion contains (as dispensed) benzoyl peroxide 5% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion.

Loroxide Acne Lotion contains (as dispensed) benzoyl peroxide 5.5%, and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion, with "Dermik Color Blender" supplied separately.

How Supplied: Vanoxide—Bottles, 25 and 50 grams; Loroxide—Bottles, 25 grams

Vanoxide-HC® and Loroxide-HC® Lotions

Description: Vanoxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.0% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion containing purified water, propylene glycol, hydroxyethylcellulose, FD&C color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, and silica.

Loroxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.5% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion containing purified water, propylene glycol, hydroxyethylcellulose, caramel color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, pH buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, silica, kaolin, talc and titanium dioxide, with "Dermik Color Blender" supplied separately.

Actions: Provides keratolytic, peeling and drying action.

Indications: An aid in the treatment of acne and oily skin.

Contraindications: Contraindicated for patients having known hypersensitivity to hydrocortisone, benzoyl peroxide, chlorhydroxyquinoline or any other component of this preparation. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia.

Warning—Usage in Pregnancy: Safety of use of topical steroids during pregnancy has not been absolutely established. Therefore, they should not be used extensively, or in large amounts or for prolonged periods of time on pregnant patients.

Precautions: For external use only. Keep away from eyes. Discontinue use if irritation develops. Use of appropriate antifungal or antibacterial agents should be instituted in presence of infection. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Observe patients carefully for possible local irritation or sensitization during long-term topical therapy. Apply with caution on neck and/or other sensitive areas. There may be a slight, transitory stinging or burning sensation on initial application which invariably disappears on continued use. Ultraviolet and cold quartz light should be employed in lesser amounts, as this lotion is keratolytic and drying. Harsh, abrasive cleansers should not be used simultaneously with this lotion. Colored or dyed garments may be bleached by the oxidizing action of benzoyl peroxide. Chlorhydroxyquinoline may cause temporary light-yellowish skin staining in rare cases. Keep out of the reach of children.

Adverse Reactions: Local adverse reactions reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneiform eruptions, and hypopigmentation. The sensitizing potential of benzoyl peroxide and chlorhydroxyquinoline are low; but they can produce allergic reaction. Reduce amount and frequency of application if excessive redness or peeling occurs.

How Supplied: Bottles, 25 grams.

Caution: Federal law prohibits dispensing without prescription.

5-Benzagel® and 10-Benzagel® Acne Gels

Description: 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent gel containing colloidal magnesium aluminum silicate, hydroxypropyl methylcellulose, citric acid, fragrance, and purified water.

Action: Provides drying, desquamative and antiseptic activity.

Indication: An aid in the treatment of acne.

Dosage and Administration: Wash affected areas prior to application. Apply once or more daily or as directed by physician.

Contraindications: Should not be used by patients having known sensitivity to either benzoyl peroxide or polyoxyethylene lauryl ether.

Precautions: For External Use Only. Not for ophthalmic use. Keep away from eyes and mucosae. Very fair individuals should begin with a single application at bedtime allowing overnight medication. May bleach colored fabrics. Keep this and all other medications out of the reach of children.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Plastic tubes, 1½ oz. and 3 oz.

Dermik

DERMIK LABORATORIES, INC.

Now!...a full family of products for intensive acne care from

Dermik

originator and leader in Benzoyl Peroxide Acne Therapy at practical patient cost

...for Benzoyl Peroxide Acne Therapy with superior, penetrating, antibacterial action...

INVISIBLE

- Vanoxide® and Vanoxide-HC® are indicated for severe, recalcitrant, oily acne.

FLESH-TINTED

- Loroxide® and Loroxide-HC® are the only tinted benzoyl peroxide products available, and they can be used as a daily make-up. These products provide the same formulation and therapeutic benefits as Vanoxide and Vanoxide-HC.
- Chlorhydroxyquinoline—benzoyl peroxide lotions provide substantially greater action than benzoyl peroxide alone. It is topical acne medication with proven ability to reduce C. acnes within the pilosebaceous structures.

For Benzoyl Peroxide Therapy in acne where maximal drying effect is desired...

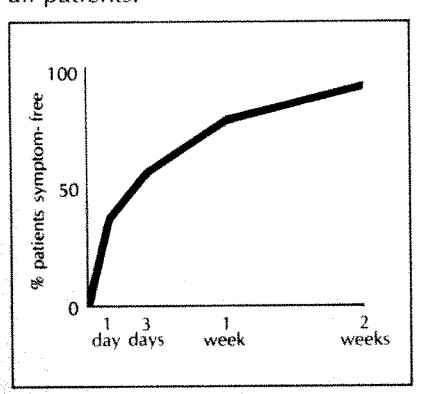
- 5 Benzagel® and 10 Benzagel® contain 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent, colloidal magnesium aluminum silicate gel vehicle.
- This combination provides superior drying action and achieves dramatic improvement in comedone and papular stages of acne ... WITHOUT EXCESSIVE ERYTHEMA OR IRRITATION.

The seven most important reasons to prescribe a topical antifungal. Right at your fingertips.

1 It is effective against the most prevalent fungal pathogens. MicaTin brand miconazole nitrate 2% offers exceptional effectiveness against the most difficult-to-treat pathogen—*Trichophyton rubrum*, and is equally effective against *Trichophyton mentagrophytes, Epidermophyton floccosum, Candida albicans* and *Malassezia furfur.*

2 It clears the most common fungal infections. MicaTin provides outstanding clinical and mycological efficacy in tinea pedis,* tinea corporis* and tinea cruris* as well as candidiasis and tinea versicolor.

3 It relieves symptoms quickly. Within 72 hours for the majority of patients. Within 1 to 2 weeks for virtually all patients.



4 It demonstrates effectiveness in extensive studies. Clinical studies† demonstrate the outstanding success rate of MicaTin in the treatment of tinea pedis, tinea corporis and tinea cruris, when used with the recommended dosage of twice daily for one month. At the end of therapy, 88—94% of the patients were clinically clear.

The clinical studies of patients with candidiasis and tinea versicolor are equally impressive. Nine out of ten patients with candidiasis or tinea versicolor were clinically and mycologically clear within two weeks—the recommended duration of treatment.

Pathogen	Infection	Conversion KOH	Culture	Clinical Clearance or Improvement
Trichophyton rubrum	Tinea pedis	82%	86%	88%
Trichophyton mentagrophytes / *Epidermophyton floccosum*	Tinea corporis / Tinea cruris	93%	90%	94%
Candida albicans	Candidiasis†	92%	86%	88%
Malassezia furfur	Tinea versicolor	89%	—	92%

5 Its low relapse rate promises an outstanding chance of cure. To prove how effective MicaTin really is in keeping fungal infections clear, we evaluated these same patients one month later (median).† Of the 121 patients who were clear of tinea pedis, tinea corporis and tinea cruris at the end of treatment *and* were available for follow-up, 92% showed no clinical or mycological recurrence of the original infection.

And of the 34 patients cleared of cutaneous candidiasis *and* available for follow-up, 91% were still clear two weeks later (median).

6 It has a low incidence of side effects. Reports of "burning" sensation, irritation and maceration with MicaTin have been few and isolated. Naturally, it should not be used in patients with known hypersensitivity to any of its ingredients.

7 It is economically priced. The retail price of MicaTin is usually lower than that of other prescription antifungals.

Introducing new
MicaTin Lotion
brand miconazole nitrate 2%
12 ml. and 30 ml. bottles
MicaTin cream
brand miconazole nitrate 2%
new 85 g. (3 oz.) tube
and familiar 1 oz. and 15 g. sizes

Description: MicaTin brand miconazole nitrate cream 2% and lotion 2% each contain miconazole nitrate‡ 2%, formulated into a water miscible base consisting of pegoxol 7 stearate, peglicol 5 oleate, mineral oil, benzoic acid, and butylated hydroxyanisole.

Actions: Miconazole nitrate is a synthetic antifungal agent which inhibits the growth of the common dermatophytes, *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* the yeast-like fungus, *Candida albicans,* and the organism responsible for tinea versicolor (*Malassezia furfur*).

Indications: For topical application in the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* in the treatment of cutaneous candidiasis (moniliasis), and in the treatment of tinea versicolor.

Contraindications: MicaTin has no known contraindications.

Precautions: If a reaction suggesting sensitivity or chemical irritation should occur, use of the medication should be discontinued.

For external use only. Avoid introduction of MicaTin brand miconazole nitrate cream 2% and lotion 2% into the eyes.

Adverse Reactions: There have been isolated reports of irritation, burning, and maceration associated with application of MicaTin.

Dosage and Administration: Sufficient MicaTin cream should be applied to cover affected areas twice daily (morning and evening) in patients with tinea pedis, tinea cruris, tinea corporis, and cutaneous candidiasis and once daily in patients with tinea versicolor. It is preferable to use MicaTin lotion in intertriginous areas; if the cream is used, it should be applied sparingly and smoothed in well to avoid maceration effects.

Early relief of pruritus (first week) and early clinical improvement (one to two weeks) have been seen in treatment of infections caused by common dermatophytes. Even though clinical improvement may be seen fairly soon after treatment is begun, *Candida* infections should be treated for two weeks and dermatophyte infections for one month in order to reduce the possibility of recurrence. If a patient shows no clinical improvement after a month of treatment, the diagnosis should be redetermined. Patients with tinea versicolor usually exhibit clinical and mycological clearing after two weeks of treatment.

How Supplied: MicaTin brand cream 2% containing miconazole nitrate at 2% strength is supplied in 1 oz., 15 g., and 3 oz. tubes. MicaTin brand lotion 2% containing miconazole nitrate at 2% strength is supplied in polyethylene squeeze bottles in quantities of 12 and 30 ml.

*When infecting organisms are *Trichophyton rubrum, Trichophyton mentagrophytes* and *Epidermophyton floccosum.*

†Data for tinea pedis is based on 4 weeks' therapy in 138 patients; for tinea cruris and tinea corporis—4 weeks' therapy in 50 patients; for tinea versicolor—2 weeks' therapy in 38 patients; for candidiasis—2 weeks' therapy in 23 patients and 4 weeks' therapy in 20 patients. (There was no significant difference in effectiveness between the two candidiasis groups.) Data on file, Dermatological Division, Johnson & Johnson.

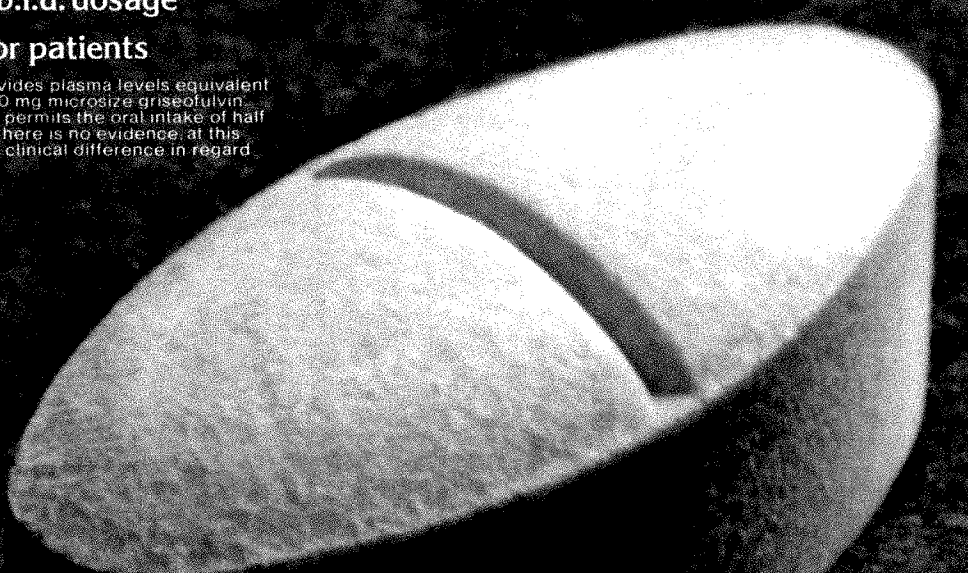
CUT THE GRISEOFULVIN DOSE IN HALF

Gris-PEG®
(griseofulvin ultramicrosize)
Tablets 125 mg

For fungal infections sensitive to griseofulvin

- Only half the dose required*
- Absorption nearly complete without fatty meals
- Once-a-day or b.i.d. dosage
- Reduced cost for patients

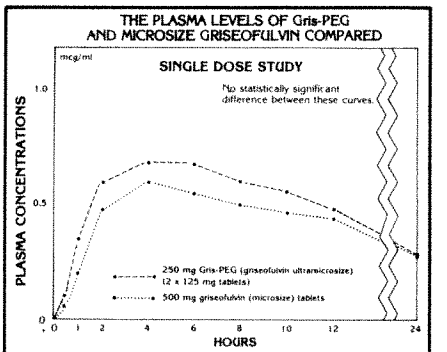
*250 mg of Gris-PEG® provides plasma levels equivalent to those obtained with 500 mg microsize griseofulvin. This improved absorption permits the oral intake of half as much griseofulvin but there is no evidence, at this time, that this confers any clinical difference in regard to safety or efficacy.



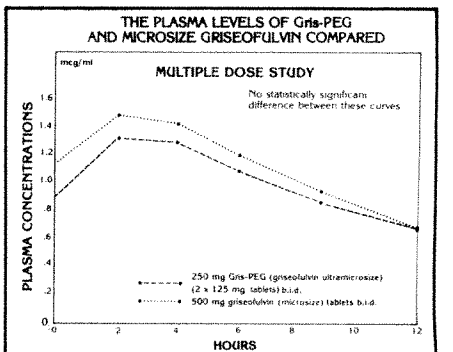
Dorsey LABORATORIES
Division of Sandoz, Inc.
LINCOLN, NEBRASKA 68501

Please see other side for full prescribing information.

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
The ½ dose griseofulvin.



Based on a single dose double-blind bioavailability study conducted in 24 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels. There is no significant difference between peak plasma levels, times to peak, and areas under the curve. Gas chromatographic assay.



Based on a double-blind multiple dose steady state crossover bioavailability study conducted in 17 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels obtained on days 9, 11 and 13. There is no significant difference between times to peak, peak plasma levels, and areas under the curve. Gas chromatographic assay.

DESCRIPTION

Griseofulvin is an antibiotic derived from a species of *Penicillium*.

Gris-PEG is an ultramicrocrystalline solid-state dispersion of griseofulvin in polyethylene glycol 6000.

Gris-PEG tablets differ from griseofulvin (microsize) tablets USP in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsize griseofulvin.

ACTION

Microbiology: Griseofulvin is fungistatic with *in vitro* activity against various species of *Microsporum, Epidermophyton* and *Trichophyton*. It has no effect on bacteria or other genera of fungi.

Human Pharmacology: The peak plasma level found in fasting adults given 0.25 g of Gris-PEG occurs at about four hours and ranges between 0.37 to 1.6 mcg/ml.

Comparable studies with microsize griseofulvin indicated that the peak plasma level found in fasting adults given 0.5 g occurs at about four hours and ranges between 0.44 to 1.2 mcg/ml.

Thus, the efficiency of gastrointestinal absorption of the ultramicrocrystalline formulation of Gris-PEG is approximately twice that of conventional microsized griseofulvin. This factor permits the oral intake of half as much griseofulvin per tablet but there is no evidence, at this time, that this confers any significant clinical differences in regard to safety and efficacy.

Griseofulvin is deposited in the keratin precursor cells and has a greater affinity for diseased tissue. The drug is tightly bound to the new keratin which becomes highly resistant to fungal invasions.

INDICATIONS

Gris-PEG (griseofulvin ultramicrosize) is indicated for the treatment of the following ringworm infections.

Tinea corporis (ringworm of the body)
Tinea pedis (athlete's foot)
Tinea cruris (ringworm of the thigh)
Tinea barbae (barber's itch)
Tinea capitis (ringworm of the scalp)
Tinea unguium (onychomycosis; ringworm of the nails)

when caused by one or more of the following genera of fungi:

Trichophyton rubrum
Trichophyton tonsurans
Trichophyton mentagrophytes
Trichophyton interdigitalis
Trichophyton verrucosum
Trichophyton megnini
Trichophyton gallinae
Trichophyton crateriform
Trichophyton sulphureum
Trichophyton schoenleini
Microsporum audouini
Microsporum canis
Microsporum gypseum
Epidermophyton floccosum

NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.

The use of the drug is not justified in minor or trivial infections which will respond to topical agents alone.

Griseofulvin is *not* effective in the following:

Bacterial infections
Candidiasis (Moniliasis)
Histoplasmosis
Actinomycosis
Sporotrichosis
Chromoblastomycosis
Coccidioidomycosis
North American Blastomycosis
Cryptococcosis (Torulosis)
Tinea versicolor
Nocardiosis

CONTRAINDICATIONS

This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.

WARNINGS

Prophylactic Usage: Safety and Efficacy of Griseofulvin for Prophylaxis of Fungal Infections Has Not Been Established.

Animal Toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.

In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.

Usage in Pregnancy: The safety of this drug during pregnancy has not been established.

Animal Reproduction Studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.

Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

PRECAUTIONS

Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic and hematopoietic, should be done.

Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.

Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.

Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.

Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

ADVERSE REACTIONS

When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion and impairment of performance of routine activities.

Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.

When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

DOSAGE AND ADMINISTRATION

Accurate diagnosis of the infecting organism is essential. Identification should be made either by direct microscopic examination of a mounting of infected tissue in a solution of potassium hydroxide or by culture on an appropriate medium.

Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. Representative treatment periods are – *tinea capitis*, 4 to 6 weeks; *tinea corporis*, 2 to 4 weeks; *tinea pedis*, 4 to 8 weeks; *tinea unguium* – depending on rate of growth – fingernails, at least 4 months; toenails, at least 6 months.

General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required particularly in treatment of *tinea pedis*. In some forms of athlete's foot, yeasts and bacteria may be involved as well as fungi. Griseofulvin will not eradicate the bacterial or monilial infection.

An oral dose of 250 mg of Gris-PEG (griseofulvin ultramicrosize) is biologically equivalent to 500 mg of griseofulvin (microsized). USP (see ACTION Human Pharmacology).

Adults: A daily dose of 250 mg will give a satisfactory response in most patients with *tinea corporis, tinea cruris* and *tinea capitis*. One 125 mg tablet twice per day or two 125 mg tablets once per day is the usual dosage. For those fungal infections more difficult to eradicate such as *tinea pedis* and *tinea unguium*, a divided daily dose of 500 mg is recommended. In all cases, the dosage should be individualized.

Children: Approximately 5 mg per kilogram (2.5 mg per pound) of body weight per day is an effective dose for most children. On this basis, the following dosage schedule for children is suggested:

Children weighing over 25 kilograms (approximately 50 pounds) – 125 mg to 250 mg daily.

Children weighing 15-25 kilograms (approximately 30-50 pounds) – 62.5 mg to 125 mg daily.

Children 2 years of age and younger – dosage has not been established.

Dosage should be individualized, as is done for adults. Clinical experience with griseofulvin in children with *tinea capitis* indicates that a single daily dose is effective. Clinical relapse will occur if the medication is not continued until the infecting organism is eradicated.

HOW SUPPLIED

Gris-PEG (griseofulvin ultramicrosize) Tablets (white) differ from griseofulvin (microsize) tablets (USP) in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsized griseofulvin. Two 125 mg tablets of Gris-PEG are biologically equivalent to 500 mg of microsized griseofulvin. In bottles of 100 and 500 scored, film-coated tablets.

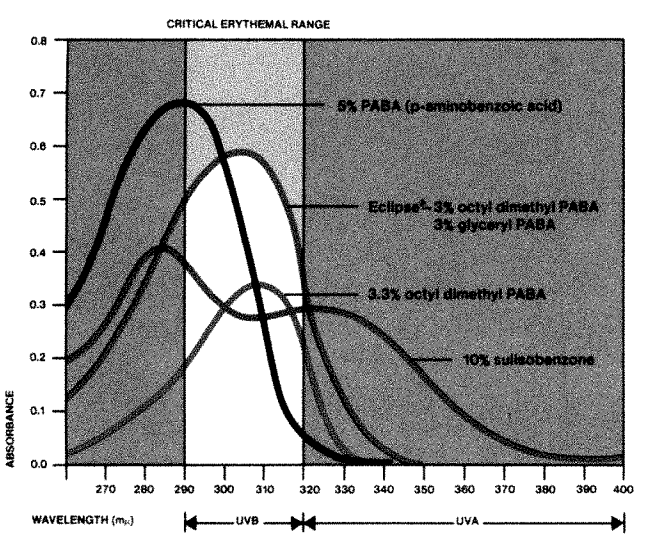
ECLIPSE®

(3% glyceryl PABA and 3% octyl dimethyl PABA)

For your patients

who can't-or won't-stay out of the sun.

For some, it's occupation. For others, the social desirability of a tan. Whatever the reason, many of your patients may be spending more time in the sun than you'd like.



Unique Eclipse formulation combines two PABA derivatives for maximum UVB absorption.

They need Eclipse—a highly effective sunscreen that works immediately upon application, resists wash-off, and contains our exclusive Aquacare® base to help relieve sun and wind-dried skin.

Can other sunscreens do all that? Take a minute to read the labels: we're confident you'll recommend Eclipse.

- Absorbs more than 99% of erythemogenic solar UVB.
- Spreads smoothly and predictably for even protection.
- Permits slow tanning.
- Resists wash-off; protects after swimming or sweating.
- Formulated in Aquacare® to relieve sun and wind-dried skin.

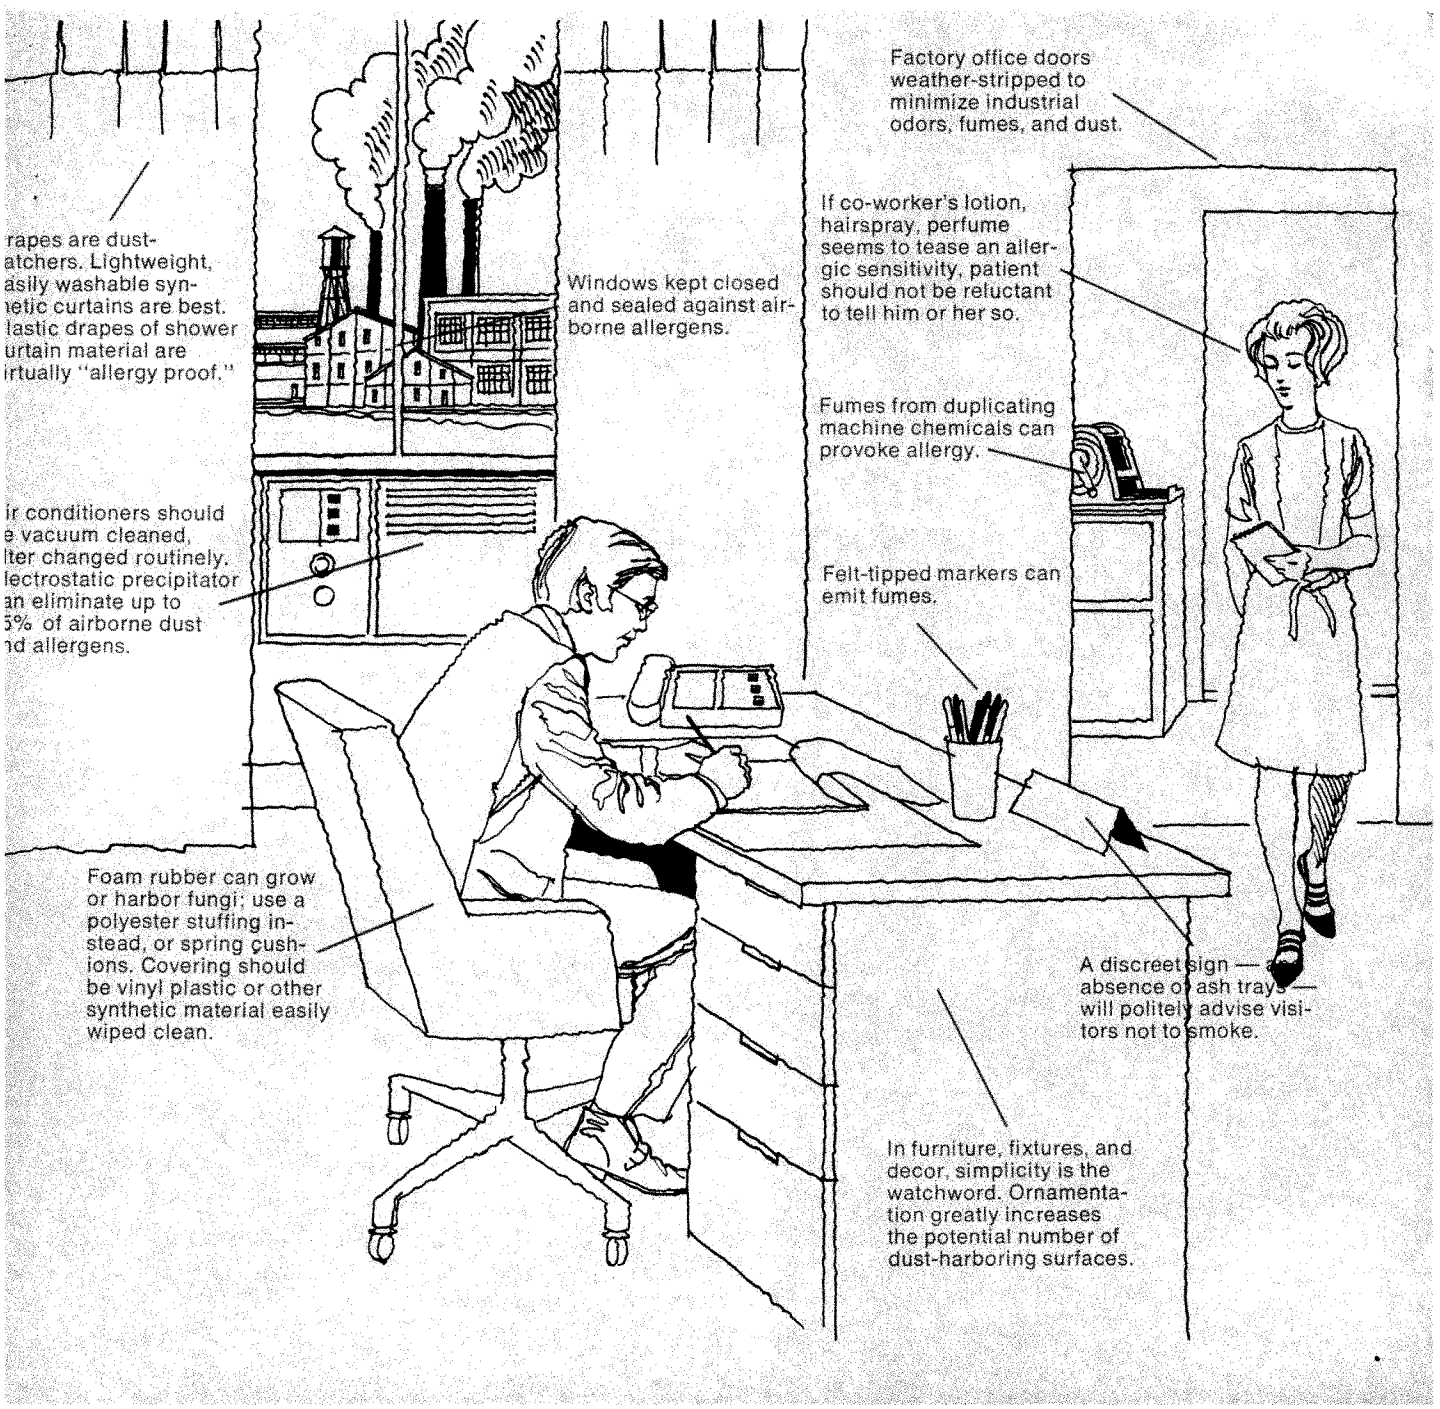
Ways to help allergy patients avoid "a bad day at the office"

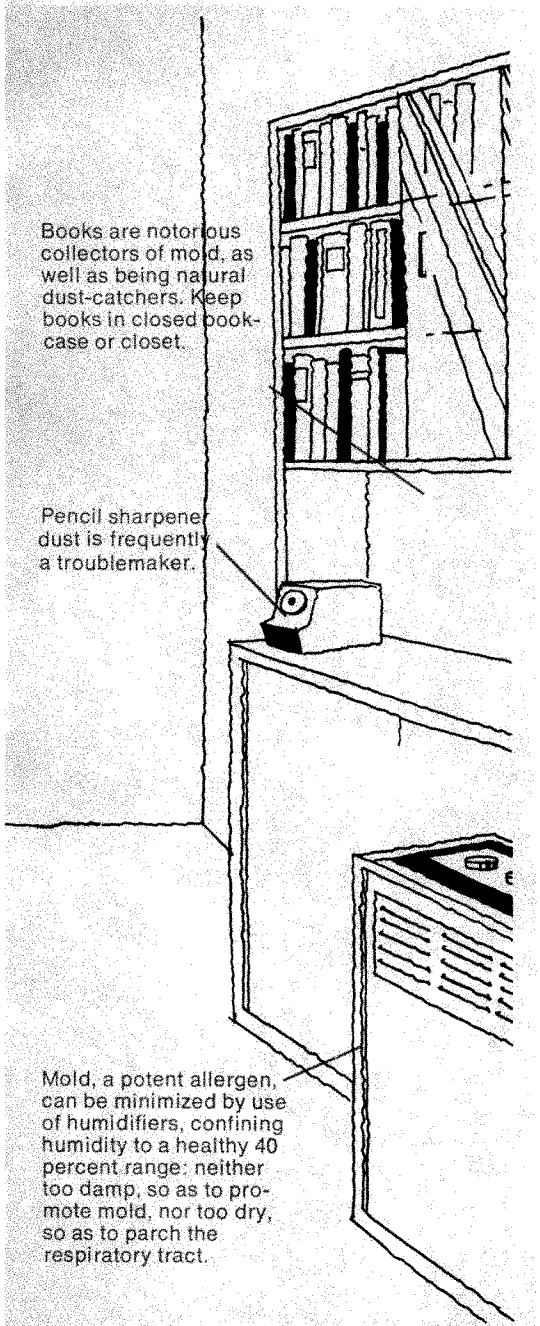
Your allergy patients who are office workers may spend a quarter of their adult life in a hostile environment — from an allergen standpoint. Here are suggestions that might, with the help of an understanding employer, lessen the allergic burden.



All measures to minimize exposure can be helpful. Still, allergic symptoms may occur and an antihistamine will be needed to bring these reactions under control. Dimetane Extentabs keep working for 10-12 hours, are economical, and are likely to produce good results in stubborn as well as routine cases, usually without drowsiness or overstimulation.

DIMETANE Extentabs®

(BROMPHENIRAMINE MALEATE, NF 8 mg. and 12 mg.)

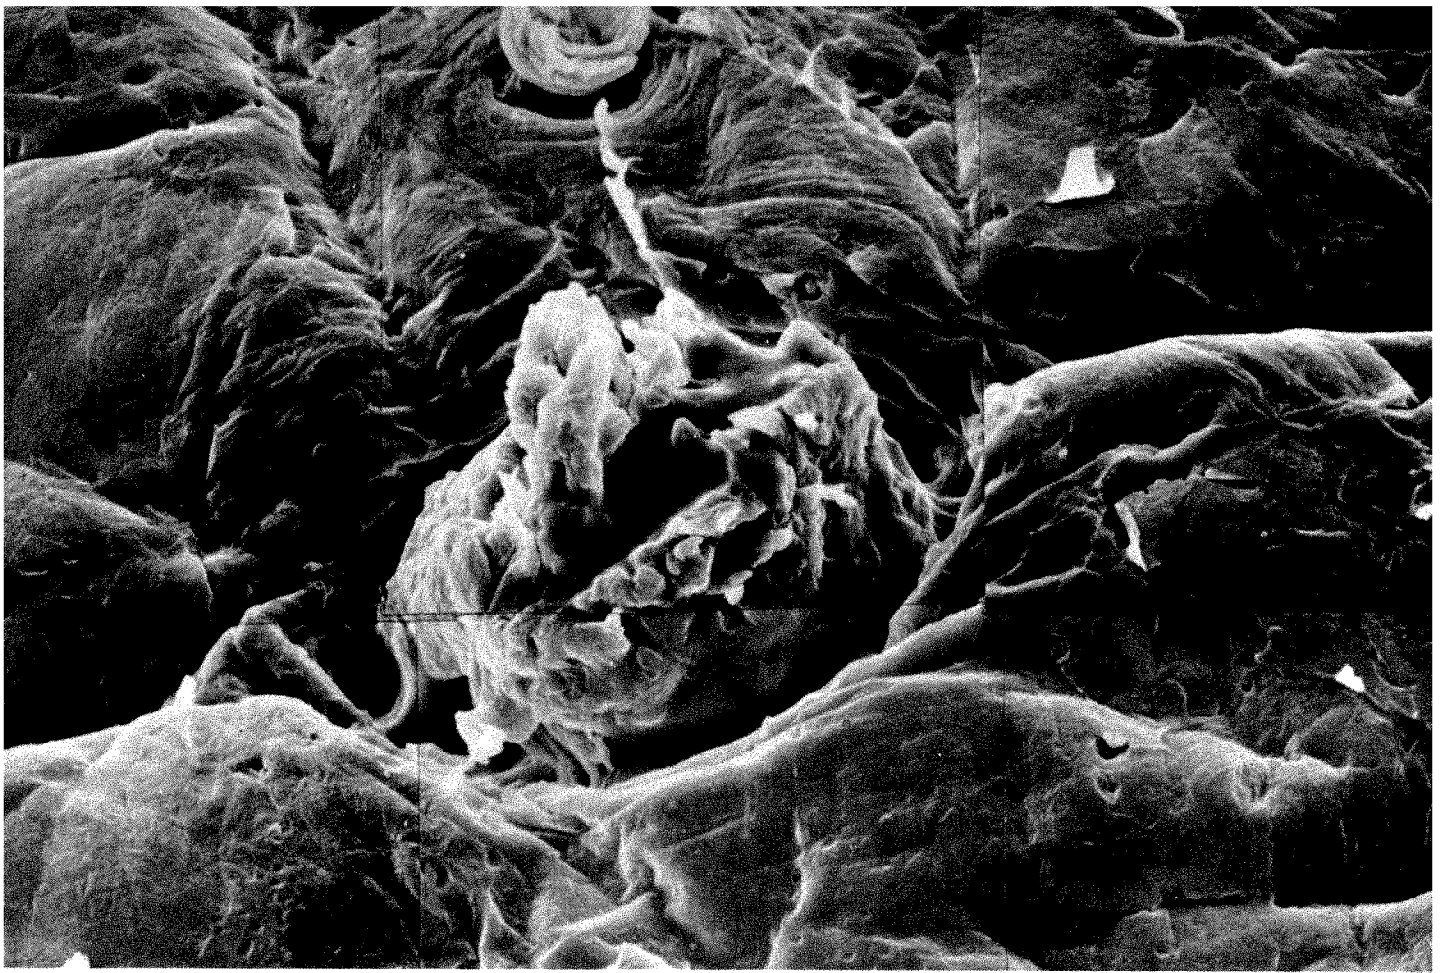


Indications: Perennial and seasonal allergic rhinitis; vasomotor rhinitis; allergic conjunctivitis due to inhalant allergens and foods; mild, uncomplicated allergic skin manifestations of urticaria and angioedema; amelioration of allergic reactions to blood or plasma; dermatographism; as therapy for anaphylactic reactions *adjunctive* to epinephrine and other standard measures after the acute manifestations have been controlled. **Contraindications:** *Use in Newborn or Premature Infants.* This drug should **not** be used in newborn or premature infants. *Use in Nursing Mothers.* Because of the higher risk of antihistamines for infants generally and for newborns and prematures in particular, antihistamine therapy is contraindicated in nursing mothers. *Use in Lower Respiratory Disease.* Antihistamines should NOT be used to treat lower respiratory tract symptoms including asthma. Antihistamines are also contraindicated in the following conditions: hypersensitivity to brompheniramine maleate and other antihistamines of similar chemical structure; monoamine oxidase inhibitor therapy (see Drug Interaction section). **Warnings:** Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma; stenosing peptic ulcer; pyloroduodenal obstruction; symptomatic prostatic hypertrophy; bladder neck obstruction. *Use in Children.* In infants and children, especially, antihistamines in **overdosage** may cause hallucinations, convulsions, or death. As in adults, antihistamines may diminish mental alertness in children. In the young child, particularly, they may produce excitation. *Use in Pregnancy.* Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus. *Use with CNS Depressants.* Dimetane has additive effects with alcohol and other CNS depressants (hypnotics, sedatives, tranquilizers, etc.). *Use in Activities Requiring Mental Alertness.* Patients should be warned about engaging in activities requiring mental alertness, such as driving a car or operating appliances, machinery, etc. *Use in the Elderly (approximately 60 years or older).* Antihistamines are more likely to cause dizziness, sedation, and hypotension in elderly patients. **Precautions:** As with other antihistamines, Dimetane has an atropine-like action and, therefore, should be used with caution in patients with: history of bronchial asthma; increased intraocular pressure; hyperthyroidism; cardiovascular disease; hypertension. **Drug Interactions:** MAO inhibitors prolong and intensify the anticholinergic (drying) effects of antihistamines. **Adverse Reactions:** The most frequent adverse reactions are italicized: *General:* Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose, and throat. *Cardiovascular System:* Hypotension, headache, palpitations, tachycardia, extrasystoles. *Hematologic System:* Hemolytic anemia, thrombocytopenia, agranulocytosis. *Nervous System: Sedation, sleepiness, dizziness, disturbed coordination,* fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesias, blurred vision, diplopia, vertigo, tinnitus, acute labyrinthitis, hysteria, neuritis, convulsions. *G.I. System: Epigastric distress,* anorexia, nausea, vomiting, diarrhea, constipation. *G.U. System:* Urinary frequency, difficult urination, urinary retention, early menses. *Respiratory System: Thickening of bronchial secretions,* tightness of chest and wheezing, nasal stuffiness. **Overdosage:** Antihistamine overdosage reactions may vary from central nervous system depression to stimulation. Stimulation is particularly likely in children. Atropine-like signs and symptoms – dry mouth; fixed, dilated pupils; flushing; and gastrointestinal symptoms may also occur. *If vomiting has not occurred spontaneously,* the patient should be induced to vomit. This is best done by having him drink a glass of water or milk after which he should be made to gag. Precautions against aspiration must be taken, especially in infants and children. *If vomiting is unsuccessful,* gastric lavage is indicated within 3 hours after ingestion and even later if large amounts of milk or cream were given beforehand. Isotonic and ½ isotonic saline is the lavage solution of choice. *Saline cathartics,* as milk of magnesia, by osmosis draw water into the bowel and therefore, are valuable for their action in rapid dilution of bowel content. *Stimulants* should **not** be used. Vasopressors may be used to treat hypotension. **Dosage and Administration:** DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO THE NEEDS AND THE RESPONSE OF THE PATIENTS. *Adults:* One to two 4 mg tablets three or four times a day. One Extentab (8 or 12 mg) every eight to twelve hours or twice daily. Two to four teaspoonfuls of elixir three or four times a day. *Children over six.* One 4 mg tablet three or four times a day. One Extentab (8 or 12 mg) every twelve hours. One or two teaspoonfuls of elixir three or four times a day. *Children under six.* 0.5 mg of brompheniramine maleate per kg of body weight per 24 hours, or 15 mg per M^2 per 24 hours, divided into 3-4 doses.

A·H·ROBINS

A. H. ROBINS COMPANY RICHMOND, VA 23220

J 015A 1800



BEFORE TREATMENT: Comedo plugged with keratinous debris. Directly above is a smaller comedo, and in the lower left hand corner a vellus hair is apparent. Note absence of sharp lines of demarcation between layers of cells.*

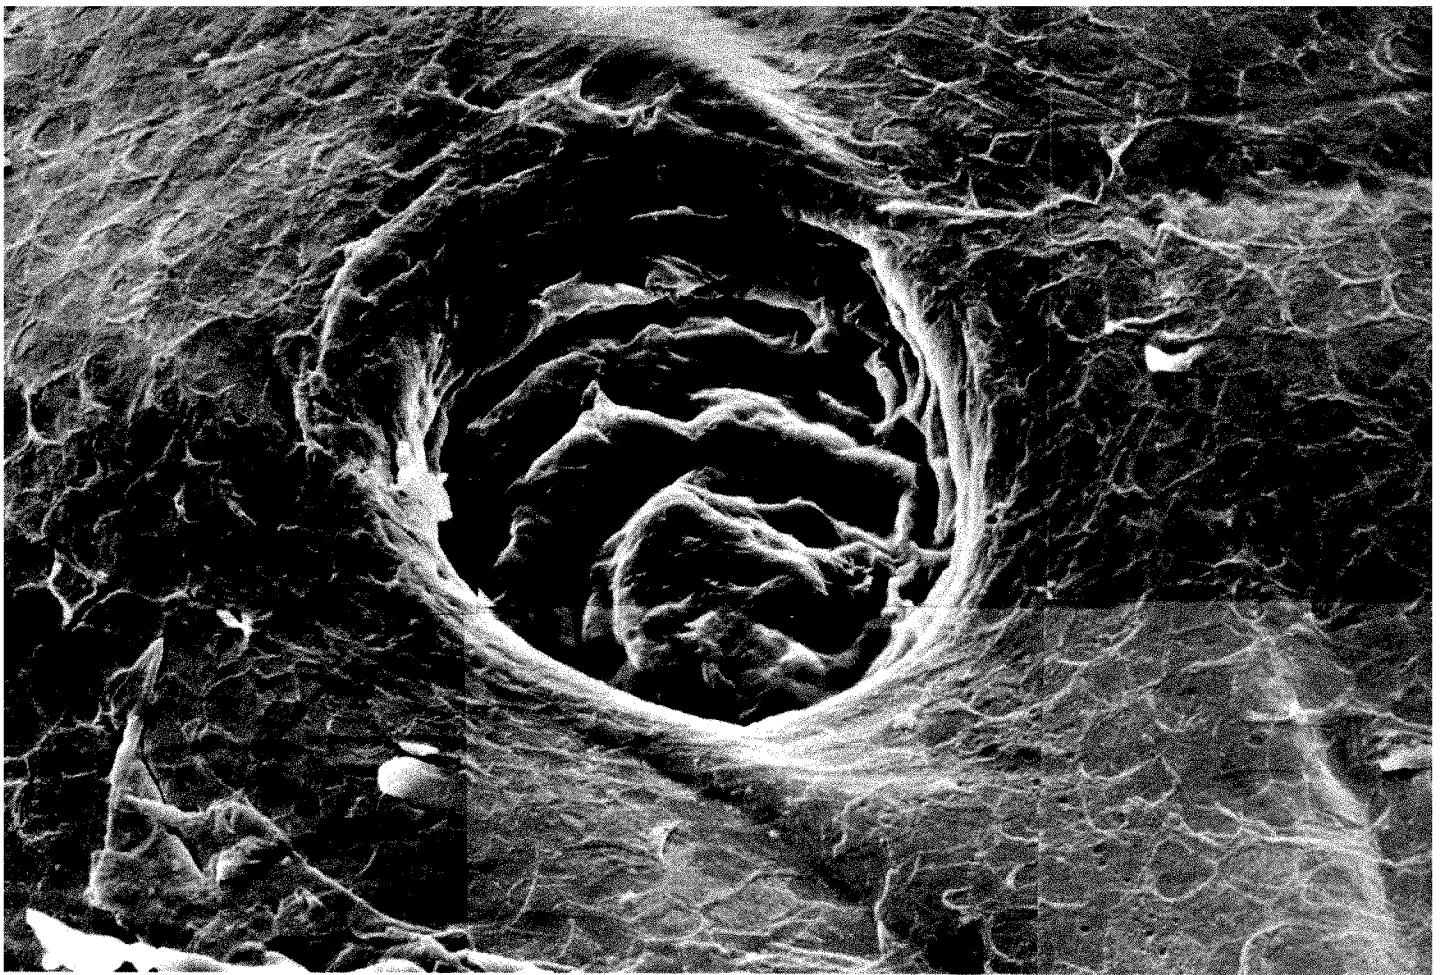
Pernox® Begins to Improve an Acne Lesion in 2 Days

Rapid resolution of an acne lesion is graphically demonstrated with Scanning Electron Microscopy.

We formulated Pernox® Abradant Scrub to make it effective yet gentle enough for acne skin.

Patients respond to Pernox rapidly, often noticing improvement after the first wash. Pernox Scrub/Lotion is a unique combination of therapeutic agents to emulsify oil and desquamate affected areas. Both forms of Pernox offer significant patient benefits.

Pernox® Lotion offers less desquamation and additional flexibility for your therapeutic acne regimen.



AFTER 2 DAYS: Depth of orifice indicates removal of plug in both large central and smaller top comedo. Surface desquamation and excellent hexagonal demarcations of individual epithelial cells are apparent.*

Pernox . . . an acne regimen formulated to give you an alternative to your present acne therapy or to be used adjunctively with other topical modalities for acne. Washing varies from patient to patient. You determine the regimen by frequency of washing and the amount of water used during the wash.

INDICATIONS: Acne vulgaris, oily skin, comedones.
CONTAINS: Gentle abradant microfine granules of polyethylene, 2% sulfur, 1.5% salicylic acid in SEBULYTIC® brand of unique penetrating surface-active combination of soapless cleansers and wetting agents.
CONTRAINDICATIONS: Not indicated when acute inflammation is present or in nodular or cystic acne.
ADMINISTRATION AND DOSAGE: After wetting the skin, PERNOX is applied with the fingertips and massaged into the skin for about one-half to one minute. The skin is then thoroughly rinsed. Used one to two times daily, or as directed.
CAUTION: If undue skin irritation develops or increases, adjust usage schedule or discontinue use. If necessary, anti-inflammatory measures may be used after discontinuance. For external use only. Contact with eyes should be avoided. In case of contact, flush eyes thoroughly with water.

*These photographs were part of a study in which participants cleansed twice daily with Pernox® Scrub.

AVEENO®
Colloidal Oatmeal
bath for sensitive skin

When you treat inflammatory diseases, such as wet dermatitis (including allergic, atopic and contact), intertrigo or wet pruritus, a colloidal oatmeal bath may prove valuable, adjunctive therapy.

Soak Away The Discomfort With AVEENO COLLOIDAL OATMEAL.

- **Cleans naturally**—a soap-free way to absorb dirt and excess oil.
- **Comforts gently**—soothingly soaks hard-to-reach and widespread problem areas.
- **Long-lasting protection**—colloidal oatmeal film continues to protect after bathing.
- **Helps restore normal skin pH.**

Available in 1 lb. and 4 lbs. boxes.

Editorial

Should Vitiligo Be Induced in Patients After Resection of Primary Melanoma?

The incidence of vitiligo is particularly high in patients who have melanomas. Indeed, one has the impression that the frequency of vitiligo increases with a prolongation of the interval between the excision of a primary melanoma and the appearance of metastatic lesions. This statement implies that vitiligo presages for the host either a prolonged remission free from the melanoma or a vigorous resistance and survival longer than expected for those without vitiligo even after metastases are found. Occasionally, patients develop vitiligo many years after the original surgical excision of a melanoma. In these patients metastases may accompany the developing leukoderma. However, the association does not negate the general principle that patients with vitiligo associated with melanomas live longer and handle their melanoma better than those with melanomas without loss of skin color.

Observations on pigs, horses, and human beings suggest that induction of vitiligo early in the course of the illness could prolong the life expectancy of the patient. The Sinclair minipig is born with benign and malignant nevocellular nevi. The animals develop total vitiligo as their tumors regress. Arabian and Lipizzaner horses are brown at birth. They develop perirectal melanomas that enlarge slowly. Their skin and hair become progressively white as the tumor grows. Based on these observations, it appears that the melanomas may precede the vitiligo. In any event horses handle their melanomas far more effectively than do human beings. Observations on man indicate that spontaneous vitiligo without BCG or vaccinia comes as a late response and that factors that cause vitiligo also retard the growth of the melanoma. One patient with vitiligo developed a melanoma. The tumor was resected and the patient may be cured because it is 19 years since the time of surgery. Another patient had extensive spread of melanoma throughout his leg and amputation was performed. After the surgery, a few cutaneous metastases grew on the stump. Those lesions were excised. The patient developed vitiligo, and he remains without recurrence for more than two years. Another patient had total vitiligo and a melanoma of many years duration before the tumor began to spread. Without the vitiligo he might have followed a more rapid downhill course.

A study should be carried out in patients whose primary melanomas are classified by depth histologically and according to the lymphocytic response. Such patients should then be treated with phenolic or catecholic compounds to produce depigmentation. Control subjects could be used, but some of the patients with melanomas could serve as their own controls because not everybody in whom one attempts to produce depigmentation will actually get vitiligo. For those patients who already have advanced disease it is important to determine the locations of their metastases and to remove as many of them as possible by surgery, x-ray, or chemotherapy. We have for a long time considered the possibility of using factors in the serum or lymphocytes from patients with vitiligo but without melanomas for the destruction of malignant melanocytes in patients with melanomas. Patients should be given serum or lymphocytes from other patients who have extensive vitiligo, but who do not have melanomas.

Can the production of depigmentation make a patient with a melanoma worse? The conditions of many patients follow a downhill course as soon as vitiligo occurs. We believe that in those situations, the host resistance has been maximum but to no avail, because it came too late. That is, the stimulus needed to get a useful immunologic response is so great that it comes only when the malignancy is far advanced. But if vitiligo could be induced early, the patient will probably have a better chance for survival.

Zinc Correction of Defective Chemotaxis in Acrodermatitis Enteropathica

William L. Weston, MD; J. Clark Huff, MD; James R. Humbert, MD; K. Michael Hambidge, MD; Kenneth H. Neldner, MD; Philip A. Walravens, MD

• Three patients with acrodermatitis enteropathica (AE), a disorder of zinc metabolism, demonstrated a zinc-responsive defect in chemotaxis of neutrophils and monocytes. Monocyte chemotaxis was depressed during a controlled period of zinc deficiency and increased to normal values after administration of oral zinc sulfate supplements that was sufficient to restore normal plasma zinc levels. In the only patient in whom neutrophils were also studied, a similar defect in chemotaxis of neutrophils was corrected by administration of zinc sulfate supplements. Preincubation of defective cells in vitro with zinc sulfate increased chemotaxis in an almost linear dose-response relationship. These findings suggest an important role for zinc in neutrophil and monocyte chemotaxis and demonstrate a correctable immune defect in AE.

(*Arch Dermatol* 113:422-425, 1977)

Acrodermatitis enteropathica (AE), a rare autosomal recessive disorder, is characterized by onset before age 1; failure to thrive; diarrhea; alopecia; a vesiculobullous eruption around the mouth, anus, hands, and feet; photophobia; glossitis; stomatitis; and susceptibility to *Candida albicans, Pseudomonas,* and other infections. For 30 years the disorder has been treated empirically with halogenated hydroxyquinoline derivatives and human breast milk. Moynahan[1,2] has recently demonstrated that the manifestations of AE are reversible by treatment with oral zinc salt supplements. Neldner and Hambidge[3] carefully reported zinc deficiency and biochemical evidence of response to zinc.[3] Most authors accept zinc deficiency as an important biochemical marker of this disease and consider AE an inherited disorder of zinc metabolism.[3-5]

Immune deficiency has been suspected in such patients because of their frequent secondary infections with *C albicans* and their ultimate death from sepsis.[6-12] One infant who died of AE was reported to have had dysgammaglobulinemia and at autopsy had a small thymus, no tonsils or Peyer patches, and no germinal centers nor IgG staining of lymph nodes.[6] This generalized lymphoid depletion was interpreted as representing both T- and B-lymphocyte deficiency. An additional child had no demonstrable thymus at autopsy.[11] Calves of the Danish black pied cattle breed also have a disease similar to AE that is characterized by severe hypoplasia of the lymphoid system and that may be reversible with zinc supplements.[13] Immunologic investigations to date in AE have been limited to the lymphocyte system.

In three patients with AE, we investigated another aspect of immunity, monocyte function. We report our findings in these three patients during a carefully monitored period of zinc deficiency and after plasma zinc levels were restored to normal by oral zinc sulfate therapy.

SUBJECTS AND METHODS

Patients

The first patient (1), a 23-year-old woman who had been treated with diiodohydroxyquin, was reported in an earlier study.[3,14] The second patient (2), a 31-month-old boy, developed typical cutaneous findings and failure to thrive at 6 weeks of age and was diagnosed as having AE at 3 months of age. He could not be treated with diiodohydroxyquin because of diarrhea and vomiting, and was treated successfully with human breast milk that was provided through a nationwide campaign. The third patient (3), a 12-year-old girl, developed diarrhea at the age of 3 months and was diagnosed as having AE at the age of 4 months. Response to diiodohydroxyquin was temporarily helpful, but due to visual disturbances, this therapy was discontinued at the age of 3 years, and she received no subsequent treatment. She demonstrated hyperkeratotic plaques around her mouth, perineum, elbows, knees, antecubital and popliteal fossae,

palms, and soles, as well as alopecia and substantial photophobia. Two older siblings had died at the ages of 6 months and 16 months with similar symptoms and signs that were suggestive of AE.

Protocol

All three patients were admitted to the Pediatric Clinical Research Unit at Colorado General Hospital. Patients 1 and 2 were withdrawn from their previous therapies and were allowed to become symptomatic with minimal dermatitis, as well as affective symptoms of depression or irritability. The three patients were studied during two clinical phases: (1) while receiving no therapy and zinc deficient, and (2) after zinc sulfate therapy had restored their plasma zinc levels to normal. Patients were given oral zinc sulfate at 4 to 9 mg/kg of body weight daily (1 to 2 mg/kg of body weight daily of elemental Zn^{++}) and were assayed for phagocyte function at 21, 4, and 9 days, respectively, after receiving oral zinc, when plasma zinc levels were restored to normal.

Laboratory Investigations

Plasma zinc levels and leukocyte studies were performed between 8:00 AM and 9:00 AM after an overnight fast. Blood was collected by peripheral venipuncture. Zinc specimens were collected in 1.5-ml polypropylene tubes that had been washed in hydrochloric acid and that contained 10 μg of heparin free of detectable zinc. Plasma samples were ashed in the oxygen plasma of a low-temperature asher prior to zinc analyses. Dissolved ash samples were analyzed spectrochemically with a silver-argon, dc-arc, and 1.5-meter direct-reading spectrometer.[15]

Quantitative monocyte studies were performed on human monocytes, as described previously.[16] Monocytes isolated from Ficoll-sodium diatrizoate gradients were suspended in a zinc-free tissue culture medium, Rosewell Park Memorial Institute (RPMI)-1640, without added serum. The mononuclear cell mixture was adjusted to 0.25×10^6 phagocytic mononuclear cells (monocytes) per chemotaxis chamber. The cells of patient 3 during the zinc deficiency stage were preincubated for 30 minutes in zinc sulfate dissolved in RPMI-1640 to make final zinc concentrations of 0.01, 0.1, and 1.0 μg/ml and then were tested for chemotaxis.[15] Similar concentrations of gluconate calcium and cupric sulfate were also investigated.

Chemotaxis was measured by the method described previously[16] with the use of microchemotaxis plastic chambers that were separated into two compartments by a sandwich of two permeable membrane filters (Millipore). An 8.0-μ filter was placed on top, and a 0.45-μ filter was placed below, which permitted counting of any cells that passed completely through the upper filter and did not adhere to its lower surface. A standard chemotactic attractant used in this assay was a 10% solution of pooled AB-negative human serum in RPMI-1640 tissue culture media activated with *Escherichia coli* lipopolysaccharide endotoxin type 0111:B4 at 200 μg/ml for 30 minutes at 37 C. This amount of endotoxin has been found to be the most effective quantity in activating the C3a and C5a components of the complement system.[16] Aliquots of 0.5 ml of endotoxin-activated serum were stored and frozen at −70 C. Attractants were added to the lower chamber, and .25 ml of a concentration of 1×10^6 monocytes per milliliter (250,000 monocytes) was added to the upper compartment. All assays were performed in triplicate. Chambers were incubated at 37 C with 5% carbon dioxide and 100% humidity for five hours. After incubation, the filters were removed, and they were fixed in absolute methanol and were rinsed in distilled water. Filters were stained with hematoxylin and bluing agents and then they were dehydrated in a standard fashion and were cleared with xylene. After they were mounted on a slide and were allowed to dry overnight, the filters were examined at a magnification of 430. Ten fields were counted. The cells on the upper surface of the 8.0-μ filter (cells that did not migrate) were compared with those migrating through the filter (including those within the filter) plus those that passed through the 8.0-μ filter and were entrapped on the surface of the 0.45-μ filter. The results were expressed as the percentage of total cells migrating by the following formula: $N = 100 \times T_1/T_2$,

where T_1 equals the total number of cells migrating, and T_2 equals the total number of cells migrating and not migrating.

Only monocyte functions were examined in patients 1 and 2. During the study of patient 3, chemotaxis of neutrophils was performed by a modified Boyden chamber technique[17] simultaneously with monocyte functions. Eosinophils were not studied. All assays were performed in triplicate, with phagocytes from healthy donors examined the same day.

Bacterial phagocytosis and bactericidal assays, phagocytosis of oil red O-containing paraffin oil particles, and phagocytosis-induced nitro blue tetrazolium (NBT) reduction were performed as described previously[16] on monocytes from the phases of zinc deficiency.

Neutrophil migration in vivo was evaluated by a new method involving plastic chambers over tape-stripped epidermis with 50% autologous serum as the chemotactant.[18] Samples were counted at 24 hours and were recorded as neutrophils per square centimeter of skin at 24 hours. Neutrophil migration was compared with that of 30 healthy young adult controls. All data were evaluated by the χ^2 method.

RESULTS

All three patients demonstrated defective monocyte chemotaxis when they were not receiving therapy (Fig 1, Table 1). Simultaneous plasma zinc levels for patients 1, 2, and 3 were 10, 47, and 30 μg/100 ml, respectively, which were well below the normal range of 68 to 112 μg/100 ml. The defective chemotaxis was corrected to normal or elevated levels (patient 2) after oral zinc sulfate supplements had increased plasma zinc values to the normal range (Fig 1).

In patient 3, assays of neutrophil chemotaxis paralleled those of monocyte chemotaxis (Table 2). Addition of zinc sulfate in vitro improved chemotaxis of both monocytes and neutrophils (Fig 2). At 0.01 μg/ml of zinc, neutrophils were more responsive than monocytes. Addition of cupric sulfate and calcium sulfate in similar concentrations had no significant effect on chemotaxis. Assays of other monocyte functions (bacterial phagocytosis, bacterial killing, phagocytosis of oil red O-containing paraffin oil particles, and phagocytosis-induced NBT reduction) were normal during zinc deficiency (Table 3). In vivo quantitative neutrophil migration into tape-stripped skin sites was normal in both the zinc-deficient and zinc-treated state at 24 hours (2.3×10^5 vs control of 1.4×10^6 leukocytes per sq cm of skin at 24 hours).

Dietary treatment with zinc sulfate reversed the symptoms and signs in all three patients. Decreased irrita-

*Mean ± 2.

bility and personality improvement were the first changes that were noted; most cutaneous manifestations cleared within two weeks.

COMMENT

Investigation of the monocyte system in these three patients showed suppressed cellular chemotaxis of monocytes during zinc deficiency, while other in vitro assays of monocyte functions (phagocytosis and bactericidal activity) were unaffected. Furthermore, in patient 3 defective chemotaxis of both neutrophils and monocytes was observed. Despite abnormal chemotaxis in vitro in our patients, neutrophil migration as measured by skin chambers in vivo was normal at 24 hours, suggesting that these two parameters of neutrophil movement depend on different determinants. Furthermore, examining the neutrophil migration at 24 hours may not uncover defects in the early stages of chemotaxis. The physiologic significance of defective in vitro chemotaxis in patients with AE is not known, but the rapid accumulation of neutrophils and monocytes at tissue sites is a crucial early event in host defenses to invading microorganisms.[17] Patients with AE do suffer from frequent and persistent infections, and this defect in chemotaxis may contribute to this susceptibility.

In addition, the defect in chemotaxis in the zinc deficiency of patients with AE was correctable by adding small amounts of zinc to defective neutrophils and monocytes in vitro. This finding demonstrated the need to study AE neutrophils and monocytes in zinc-free medium. Normal neutrophils and monocytes did not demonstrate improved chemotaxis with the addition of zinc sulfate, nor did cupric sulfate or gluconate calcium salts improve faulty chemotaxis in patient 3.

Immunity in patients with AE has been infrequently studied in the past.[6-11] The two autopsy studies to date showed diminished thymic tissue and generalized lymphoid depletion. However, in both cases, prolonged malnourishment, diarrhea, and failure to thrive may account for lymphoid changes occurring as a terminal event rather than preceding signs of AE. The Danish cattle breed with zinc deficiency and with signs and symptoms of AE often die at the age of 4 to 5 months with generalized lymphoid depletion. Their extreme state of malnutrition may result in this depleted lymphoid system as in the two children who were the subjects of the autopsy reports.[3] No requirements for zinc in human immune function have been described.

Evidence that zinc affects phagocytic cells has been observed in mice that were treated with low doses of zinc, which resulted in increased viability of their peritoneal macrophages when exposed to toxic doses of silica. Both low-dose and high-dose zinc treatment resulted in impaired phagocytosis of *Staphylococcus aureus* by mouse macrophages.[19] Furthermore, zinc also may serve as a cofactor to aid the spreading of mouse macrophages on glass surfaces.[19] These animal studies suggest that zinc expresses activity on phagocyte membranes.

Identification of a correctable immune defect in AE during zinc deficiency broadens our understanding of this disease. Furthermore, it suggests that zinc may play a crucial role in monocyte and neutrophil chemotaxis.

This study was supported by a grant from the National Live Stock and Meat Board; by grant RO1-AM-1243 from the National Institute of Arthritis, Metabolic and Digestive Disease; and by grant RR-69 from the General Clinical Research Centers program of the Division of Research Resources, National Institutes of Health.

Selma Targovnik, MD, and Archie McIntosh, MD, referred patients 2 and 3.

Autoimmune Progesterone Dermatitis

Roland Hart, MD

• **Seven patients had autoimmune progesterone dermatitis. The morphological findings illustrate the polymorphous nature of the disease in which urticaria, erythema multiforme, and dyshidrosiform lesions were seen. Recurrence of the eruption five to ten days prior to the menses with spontaneous resolution following the menses was present in all cases. Intradermal skin testing to progesterone was done to confirm the diagnosis. Six of the seven patients had a history of use of artificial progestational hormones prior to the beginning of their eruption. It is postulated that the artificial progesterones may have been the trigger for the development of their autosensitivity. Treatment with conjugated estrogens resulted in remission of the disease in five of the seven cases reported.**

(*Arch Dermatol* 113:426-430, 1977)

To date there have been seven cases reported in the literature of skin diseases caused by progesterone that seemed to represent an autoimmune disease. Two of the cases reported were urticarial and five were nonurticarial. Only one case was reported in a pregnant woman.

The concept of an autosensitivity to one's own progesterone could be considered analogous to other autoimmune diseases such as lupus erythematosus and pemphigus in which there are circulating antibodies directed against autologous tissues.

Seven patients are reported herein with progesterone dermatitis, five of which were successfully treated with anovulatory drugs. In addition, a review of the literature and of normal female progesterone function is presented, and an hypothesis is offered as a possible etiology of this disease.

REPORT OF CASES

CASE 1.—This 29-year-old college English teacher came to the Dermatology Clinic on Dec 3, 1973, with a six-month history of a markedly pruritic vesicular eruption on the palms and soles. The eruption on the soles prevented her from standing or walking without severe pain. She had been treated previously with tolnaftate (Tinactin), a mixture of nystatin, neomycin sulfate, and triamcinolone (Mycolog), hydrocortisone, and 0.1% triamcinalone (Kenalog) creams, all of which reduced the pruritus, but the eruption continued to recur.

At the time of her initial examination in the clinic, she was taking no drugs other than an occasional aspirin. She had taken birth control pills previously, but none since the eruption began. She had no known sensitivities. Her family history was negative for skin disease.

On initial physical examination there were vesicles and pustules on the palms and soles (Fig 1 and 2) and an erythematous, macular, and papular eruption on the arms and legs. A KOH preparation and fungal cultures were negative.

Initially, she was given an emulsion ointment (Cetaphil) as a replacement for soap and water baths, 0.1% triamcinolone cream, and Burrows soaks to the feet.

Additional history on the next visit revealed that, since the beginning, her eruption had been flaring cyclically just prior to her menses and clearing with or without treatment as the menses began. However, each flare was worse than the previous one.

On this visit, intradermal skin tests to progesterone and *Candida* were administered. One of the nurses in the clinic also received progesterone skin tests to serve as

a control. After 48 hours, the patient's progesterone tests showed 6 mm induration and 2 cm of erythema and was interpreted as positive (Fig 3). The nurse's control tests were negative.

In December 1973, conjugated estrogens (Premarin), 1.25 mg/day, was begun for a 21-day cycle, and she was referred to gynecology for breast and pelvic exams.

The January 1974 follow-up showed no vesiculation, no weeping, and no oozing throughout the entire cycle.

However, in April 1974, a few vesicles developed and the conjugated estrogens were increased.

In June 1974, she was completely clear and was switched to norethynodrel (Enovid E). During the next two cycles, she flared, the norethynodrel therapy was discontinued, and regimens of conjugated estrogens, 1.25 mg/day, were begun, and she again cleared.

In June 1975, the conjugated estrogens were reduced to 0.625 mg/day and when she was last seen in December 1975, she was still free of skin lesions.

Case 2.—This 25-year-old housewife presented in July 1973 with a seven-year history of a bullous eruption on the mouth, chest, back, and arms. Historically, the eruption began five days prior to the menses with resolution following the menstrual flow. Her eruption was initially felt to be related to birth control pills she was taking and they were stopped; however, her eruption continued to recur cyclically. Skin biopsy results were consistent with bullous erythema multiforme.

Past medical history revealed she had a

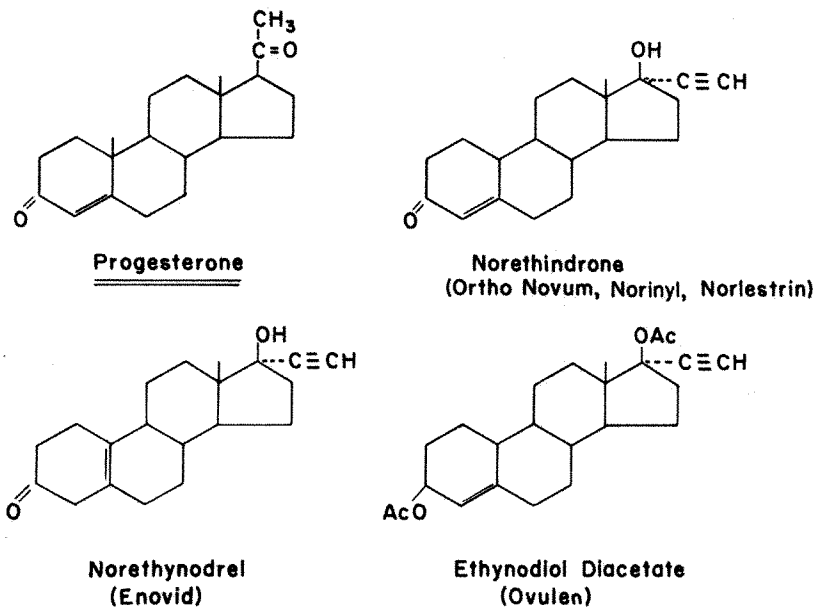

Fig 6.—Comparison of progesterone with synthetic progestins.

unilateral oophorectomy because of an ovarian cyst.

Initial examination revealed multiple vesicles on an erythematous base on the upper back, face, and arms. No oral lesions were observed.

Skin tests to progesterone were administered intradermally and were positive at 48 hours.

Regimens of conjugated estrogens were started. Follow-up one month later showed her to have had a completely lesion-free cycle. In September, she was switched to norethynodrel, and during the next cycle, she again developed bullous lesions prior to the menses. The conjugated estrogen therapy was again initiated and she has remained free of lesions since.

CASE 3.—This 40-year-old typist presented in March 1974 with a three-year history of a bullous eruption on the extremities and mouth. The eruption occurred cyclically and appeared seven to ten days prior to the menses and resolved following the menses. There was no history of any drug ingestion, herpes, or recurrent strep infection. She had a proven allergy to penicillin and a history of hay fever.

Past history revealed a previous Papanicolaou smear showing low estrogen effect.

Examination revealed erythematous target-like vesicles on both hands (Fig 4), wrists, knees, and shins. There was an erosive lesion on the left buccal mucosa. Skin biopsy results were consistent with bullous erythema multiforme.

She was admitted to the hospital for workup of erythema multiforme. The workup results were normal except for intradermal skin tests to progesterone that showed 1.5 cm erythema and 7 mm induration. Conjugated estrogen therapy, 1.25 mg/day, was begun.

In May 1974, follow-up revealed no eruption. Subsequently she married, moved, and was lost to follow-up.

CASE 4.—This 30-year-old woman came to Redwood City Kaiser Dermatology Clinic in October 1972 with a seven-year history of a chronic, symmetrical dermatitis of the feet and a few vesicles on the hands. She was initially treated with systemic steroids. Patch tests to the 14 most common sensitizers listed by the North American Patch Test Group were applied and revealed 1+ to formalin, 1+ to neomycin, and 4+ to ethylenediamine. Betamethasone valerate (Valisone) ointment was then prescribed but gave no relief.

Intralesional triamcinolone diacetate (Aristocort) injections were subsequently given around the tenth day of August, September, October, November, December, January, and February without significant results. A KOH preparation and fungal cultures were negative in May 1974, and a skin biopsy taken at that time revealed hypertrophic lichen simplex chronicus.

On June 4, 1974, a history of occurrence of the eruption just prior to each menses was obtained. In July 1974, progesterone, 25 mg intramuscularly, was given as a provocative test, and severe pruritus with vesiculation occurred on the feet.

Consequently, therapy with ethinyl estradiol (Estinyl), 0.02 mg daily, was begun with resolution of her problem for two cycles. However, she was unable to continue estrogen therapy because of endometriosis. Oophorectomy is being contemplated.

CASE 5.—A 48-year-old woman had a one-year history of chronic urticaria, angioneurotic edema, and laryngeal spasm necessitating self injections of epinephrine (Adrenalin). She was treated on several occasions with hydroxyzine pamoate (Vistaril), desensitization injections, corticosteroids, adrenocorticotropic hormone, strict elimination diets, and oral and vaginal nystatin (Mycostatin) without much improvement.

She gave a history of her urticaria initially occurring in cyclical patterns ten days prior to the end of each month, but by the time of her presentation in the clinic, the urticaria was almost constant with exacerbation of laryngeal spasm occurring at the end of each monthly cycle.

Past medical history revealed recurrent aphthous stomatitis, chronic allergic rhinitis, hypothyroidism, total abdominal hysterectomy, nephrolithiasis, pityriasis rosea, and lumbar disc disease with laminectomy and fusion.

Medications at the time included thyroid USP, propranolol hydrochloride (Inderal), hydroxyzine, tripelennamine (Pyribenzamine), and epinephrine as needed.

Physical examination revealed small 5 to 6 mm urticarial lesions and a dermographism response.

She was admitted to the hospital and subsequent laboratory test results, including those from chemistry screening battery II, lupus erythematosus preparation, urinalysis, porphyrins, fluorescent antinuclear antibody, complete blood cell count, antinuclear antibody, stool guaiac, ova and parasites, and challenge to salicylates, were negative. Abdominal x-ray film revealed residual pantopaque from her myelogram and splenic calcifications from old granulomatous disease. Chest x-ray film revealed old calcifications of the right hilar nodes. Follicle stimulating hormone levels were 7.0, and basal body temperature ranged from 36 C (96.8 F) to 36.1 C (97 F) with an increase to 37.2 C (99 F) for three days. These latter two studies suggested she was not postmenopausal and was ovulating. Intradermal skin tests to progesterone produced noticeable urticaria after 20 minutes (Fig 5) and positive

delayed hypersensitivity at 48 hours. Intermediate purified protein derivative, cocci, and *Candida* test results were negative; mumps was positive. Saline control was negative at 20 minutes and negative at 48 hours. A nurse-assistant control was negative for progesterone.

On discharge, she was placed on regimens of bromodiphenhydramine hydrochloride (Ambodry), chlorpheniramine maleate (Teldrin), and hydroxyzine. Her urticaria continued, as did her laryngeal edema, requiring epinephrine and systemic steroids.

In October 1974, therapy with conjugated estrogens was started, and one week later, fewer urticaria were observed.

In November, some urticaria were still present and the regimen of conjugated estrogens was increased. Because of another episode of laryngeal spasm, the dosage had to be increased once more to alternating doses of 2.50 and 1.25 mg/day. This produced clearing of her urticaria. She was seen again in January 1975, and was free of urticaria, but had edema of the lower extremities so her dosage was decreased. One week later, she was free of urticaria and had decreased fluid retention.

When last seen in November 1975, she had been free of urticaria for six months and on no antihistamines.

Case 6.—This 34-year-old woman had a four-month history of urticaria that occurred prior to her menses. Historically, she received an injection of medroxyprogesterone acetate (Depo-Provera) in August 1972 and another in November 1972. She developed an eruption diagnosed as pityriasis rosea in January 1973. She received a third injection in February, following which she developed definite urticaria. In March, April, May, and June, she had cyclical urticaria with no relief from antihistamines and subsequently was placed on prednisone, 10 mg daily each month, when the urticaria began through her menses. She was lost to follow-up for 1½ years. A phone conversation with this patient in September 1975 revealed that her urticaria had continued cyclically for 18 months and then resolved. She is still menstruating, but it is unknown whether she continues to ovulate.

Case 7.—This 29-year-old woman developed generalized erythema multiforme in February 1972, after taking norgestrel (Ovral) for one month. This eruption continued to occur monthly approximately 10 to 14 days prior to the menses even though the norgestrel had been discontinued. On two occasions, she was diagnosed as having Stevens-Johnson syndrome and required treatment with systemic steroids. Over the last two years, she has had several emergency room visits in which she was given systemic steroids for relief of erythema multiforme.

Physical examination on Sept 3, 1975, revealed target lesions on the hands, elbows, and back and vesicles on the buccal mucosa.

On administration of progesterone skin tests intradermally in September 1975, urticaria were noted around the progesterone and mumps injection sites in 15 minutes but not around a saline control site or *Candida*. At 48 hours, there was 6 mm duration and 8 mm erythema at the progesterone sites, and these were interpreted as positive. The mumps were also positive. Skin biopsy was consistent with erythema multiforme. Direct immunofluorescence was negative. Indirect immunofluorescence using human and rat corpus luteum was positive at 1:5 and 1:10 dilutions.

Treatment with conjugated estrogens, 1.25 mg/day was begun at the time of submission of this paper.

BRIEF REVIEW OF THE LITERATURE

In 1951, Guy et al[1] reported a case of a 28-year-old woman with a history of generalized urticaria of six years' duration that occurred premenstrually each month.

In 1964, Shelley et al[2] reported a 27-year-old woman with a vesicular eruption of five years' duration who had regular premenstrual exacerbation that could be elicited by giving progesterone and progesterone compounds. In addition, basophil degranulation was found to be marked and was followed by basopenia. They were able to suppress her eruption with estinyl estradiol. Attempts at desensitization to progesterone failed. She underwent oophorectomy and remained free of disease.

Tromovitch and Heggli,[3] in 1967 reported a case of progesterone urticaria in a 20-year-old woman and successfully treated her with conjugated estrogens, 1.875 mg/day. Of interest in this case was that challenge with 20 mg intramuscularly injected progesterone gave an immediate reaction that had to be controlled with epinephrine and steroids.

Jones and Gordon,[4] in 1969, reported a case involving a 17-year-old with pruritus and erythematous, eczematous papules that flared premenstrually. They were able to demonstrate in vitro indirect basophil degranulation.

Farah and Shbaklu,[5] in 1971, described two patients with premenstrual urticaria and were able to demonstrate positive skin tests to progesterone, passive cutaneous transfer, and positive indirect immunofluorescence of IgG antibodies to the luteinizing cells of the corpus luteum.

Bierman, in 1973,[6] presented a 25-year-old woman with papules, pustules, hyperpigmentation, and erosions on the arms, legs and buttocks, and spontaneous abortions of each of her two pregnancies. She demonstrated positive skin tests to progesterone; however, skin immunofluorescence was negative. She was successfully treated with conjugated estrogens.

Meltzer,[7,8] in a report to the Southern Medical Association in 1961, presented several patients with endocrine hypersensitivity. Interestingly, two of his cases appeared to have been exogenously sensitized to progesterone. He suggested that exogenous as well as endogenous hormones may stimulate antibody formation.

REVIEW OF PROGESTERONE FUNCTION

Progesterone is the principal hormone of the corpus luteum and is derived from cholesterol. In addition to the two-carbon side chain at position 17, progesterone possesses a ketone function at carbon 20 and the Δ^4 three keto grouping in ring A. Its chief source is the corpus luteum, but it is also found in small amounts in the serum of the ovarian, placental, adrenal, and peripheral veins.[9] Pregnanediol is its major known metabolite. The liver is the major site of conversion of progesterone.

Forbes[10] has demonstrated progestational activity in the blood of ovulating woman reaching a maximum between the 20th and 21st day of the cycle. Assays of corpus luteum shows first measurable progesterone on the 14th day. Johansson,[11] from Sweden, has perfected a simplified method of assaying plasma progesterone uti-

lizing petroleum ether extraction followed by competitive protein binding analysis.

Radioimmunoassay studies in humans by Yussman[12] show a dramatic rise in progesterone or total progestin 24 to 48 hours prior to ovulation. These studies suggest "that this rise is not dependent upon ovulation alone but is also a product of the still unruptured but developing follicle or perhaps, of other atretic follicles."

Progesterone's main function is to prepare the uterus for implantation of the ovum. It also affects the cervical mucous secretion, is responsible for the acinar and lobular development of the breast, and causes increased body temperature.

The synthetic progesterones are made by adding or modifying side chains (Fig 6). Most are derived from 19-nortestosterone, 17α hydroxyprogesterone, or acetoxyprogestin.

All seven patients presented are similar in that, their eruptions began seven to ten days prior to the menses. In addition, their eruptions tended to clear spontaneously following the menstrual flow. In each case, estrogen therapy suppressed the disease. All skin testing was done intradermally, using aqueous progesterone suspension 100 mg/ml. This was diluted with normal saline to 0.1 mg/ml, 0.01 mg/ml, and 0.001 mg/ml. In each case mumps and *Candida* intradermal skin tests were administered as a control. One of the clinic nurses served as an additional control.

In case 4, provocative testing was done, using 25 mg progesterone suspension intramuscularly.

Historically, six of our patients were noted to have taken exogenous progesterones at some time prior to the beginning of their eruption. The oral contraceptives are similar in structure but dissimilar enough to possibly induce antibody formation in susceptible individuals. It seems that artificial progestins may have been the trigger for the disease in six of our patients.

In case 1 and 2, it is noted that both patients flared when given norethynodrel. This seems to further suggest that there was cross reactivity between artificial progesterone and endogenous progesterone.

The following outlines our series of patients and their use of prior hormones:

	Prior Use of Hormones
Case 1	Yes, norethindrone (Norinyl)
Case 2	Yes, brand unknown
Case 3	No?
Case 4	Yes, brand unknown
Case 5	Yes, brand unknown
Case 6	Yes, medroxyprogesterone acetate
Case 7	Yes, norgestrel

The positive indirect immunofluorescence indicates the presence of circulation antibodies against the cells of the corpus luteum. The fluorescence is seen within the cytoplasm of the luteinizing cells. It is believed this is where the production and/or secretion of progesterone takes place.

The hormonal and immunological functions of the body are complex. The increasing use of synthetic drugs may be adding a new dimension to the etiology of hormonal disturbances and may be mediated by the induction of immunological reactions with cutaneous manifestations in susceptible patients, as we see in drug induced lupus erythematosus for example.

In patients with a cyclical eruption related to the menses, this entity should be strongly considered.

Alvin J. Cox, MD, Denny Tuffanelli, MD, and Betty Russell assisted with the immunofluorescence.

Transient Acantholytic Dermatosis

A Reevaluation

Marc Chalet, MD; Ralph Grover, MD; A. Bernard Ackerman, MD

• **Transient acantholytic dermatosis is a self-limited, primary acantholytic disease that occurs predominantly in persons over 50 years old. The primary lesions, discrete papules and papulovesicles, are distributed mainly on the chest, back, and thighs and may be intensely pruritic. The disease lasts less than three months in the majority of patients, but occasionally may go on for two or three years.**

Four distinct histologic patterns are present in the biopsy specimens, namely, Darier-like in which there is focal acantholysis and dyskeratosis overlying suprabasilar clefts; pemphigus vulgaris-like, in which there are a few acantholytic cells above discrete suprabasal clefts having a mostly intact overlying epidermis; Hailey-Hailey-like, in which there are numerous acantholytic cells overlying suprabasilar clefts; and, finally, spongiotic, in which a few acantholytic cells are present within, or contiguous with, spongiotic foci. Some cases show a predominance of one pattern, but more frequently two or more of these patterns can be found in a single biopsy specimen.

(*Arch Dermatol* 113:431-435, 1977)

Transient acantholytic dermatosis (TAD) was described in 1970.[1] In the original and subsequent[2] reports, the disease was characterized as pruritic and self-limited. The lesions were papules and/or papulovesicles and were predominantly distributed on the chest, back, and thighs of older persons. Results of histologic and electron microscopical examination showed either acantholysis that mimicked Hailey-Hailey disease,[3] or acantholysis and dyskeratosis that resembled Darier disease.[4] Ackerman has proposed the term "focal acantholytic dyskeratosis"[5] as an appropriate label for this latter general category of histologic change.

Transient acantholytic dermatosis has apparently become increasingly well recognized, as judged by our experience in private practice and by the patients sent to the dermatopathology laboratory of the New York University Medical Center. On the basis of our increased experience, we believe that some features of the original clinical description should be amended, and the histologic features should be described in more detail.

Accepted for publication June 28, 1976.

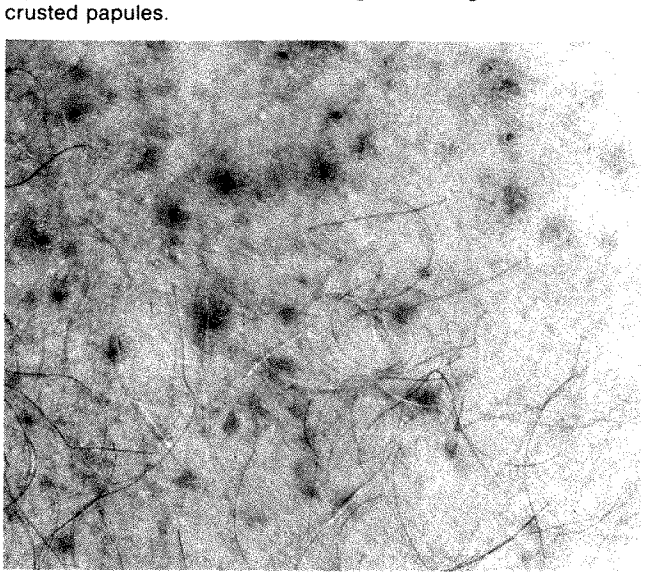
PATIENTS AND METHODS

For the clinical aspects of the study, 54 patients with TAD seen by one of us (R. W. G.) were reviewed. The clinical diagnosis was supported in each patient either by histologic[2,3] or cytologic[3,4] examination, or both. When a Tzanck smear showed acantholytic cells from a lesion of a patient with the clinical features of TAD, the diagnosis was deemed to be confirmed.

For the histologic portion of the study, we reviewed 40 cases of clinically diagnosed TAD. Of these, 19 came from the files of the dermatopathology laboratory of New York University Medical Center, and

Fig 1.—Discrete papulovesicular lesions on "V" of chest in elderly man.

Fig 2.—Closer view of lesions in Fig 1 showing edematous and crusted papules.



the rest were from the group used in the clinical study noted in the previous paragraph. Step sections were cut through the specimen in every case.

RESULTS
Clinical Features

The general characteristics previously reported[1,2] were confirmed. All of the patients, save one, were over age 40. The one exception was three months short of being 40 years old when his disease began. The course of the disease usually was relatively brief. In two of three patients it lasted from two weeks to three months, but it continued for a year or more in four instances. In one of these patients, the disease lasted for two years. Another patient (from the group of patients in the New York University records) still had his disease at the end of three years and has been reported elsewhere.[6]

The lesions of TAD occur primarily in four areas: about the clavicles, the lower anterior aspect of the rib cage, the upper portion of the chest (Fig 1), the back, and the lumbar area. The disease may begin in any of these areas and may remain limited to a few discrete papules or papulovesicles (Fig 2). When the eruption is more extensive, several or all of the areas may be involved, as may be the deltoids and the lateral aspects of the neck and thighs. Lesions affect the scalp infrequently and have not been seen to involve mucous membranes, palms, or soles.

The individual lesions of TAD vary from edematous papules or papulovesicles to keratotic and/or papules. The keratotic papules resemble those of Darier disease. Contrary to the impression given by the photographs in the original report,[1] the lesions are usually sparse and remain discrete. Confluence is infrequent. Because pruritus is common and is often severe, many papules may be excoriated.

The clinical characteristics of TAD are often subtle, and diagnosis requires a high index of suspicion. Transient acantholytic dermatosis may be mistaken for acne, seborrheic dermatitis, miliara rubra or folliculitis. In the more intensely pruritic patients, TAD may be confused with scabies

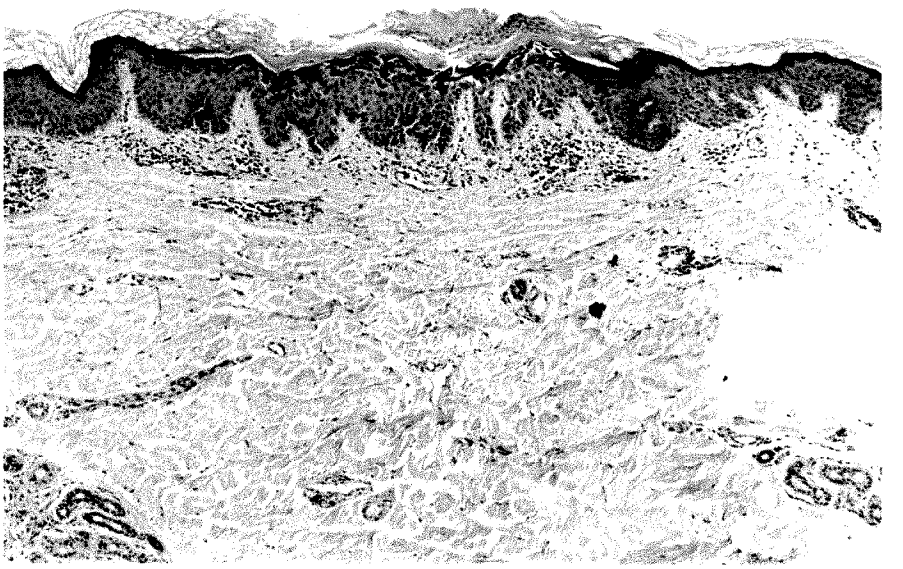


Fig 3.—Well-circumscribed focus of Darier-like changes in patient with transient acantholytic dermatosis (hematoxylin-eosin, original magnification ×16).

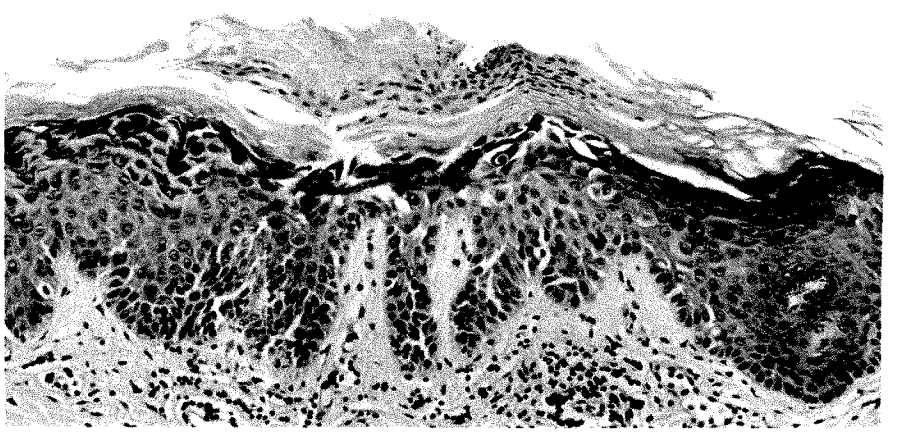

Fig 4.—View at higher power of changes shown in Fig 3 showing suprabasilar clefts and acantholytic, dyskeratotic cells in granular and spinous layers. Alternating vertical orthokeratosis and parakeratosis here seen is unusual in Darier disease (hematoxylin-eosin, original magnification ×40).

and dermatitis herpetiformis.

Eleven of the patients with TAD had been exposed to excessive natural sunlight during the month prior to the onset of their disease, usually during winter vacations in Florida. In only three did the disease start in the summer months.

TAD was associated with asteatotic dermatitis in six patients, and with psoriasis in eight others. In the latter group, three patients had eruptive psoriasis which had been triggered either by injudicious ultraviolet therapy or by an irritative reaction to anthralin.

Histologic Features

Four histologic patterns were seen within the epidermis. Two or more of these patterns might be found in the same specimen. The first of these histologic changes was a focal, acantholytic dyskeratosis resembling Darier disease (Fig 3 and 4). Above suprabasal clefts there were acantholytic and dyskeratotic cells at all levels of the epidermis, as well as parakeratosis. In some instances, the cornified layer had a normal basket-weave configuration. These Darier-like changes were seen by themselves in eight of the cases, and in association with other histologic patterns in five cases.

Fig 8.—View at higher power of changes in Fig 7 showing suprabasilar clefts and acantholytic cells at all levels of epidermis (hematoxylin-eosin, original magnification ×160).

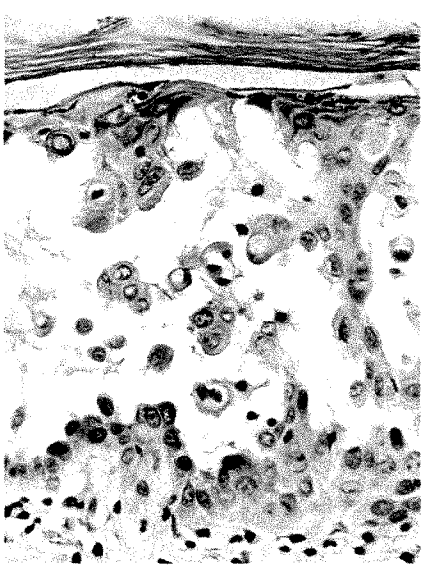

Fig 9.—Focal changes that resemble those of superficial pemphigus (foliaceous and erythematosus) in patient with transient acantholytic dermatosis (hematoxylin-eosin, original magnification ×40).

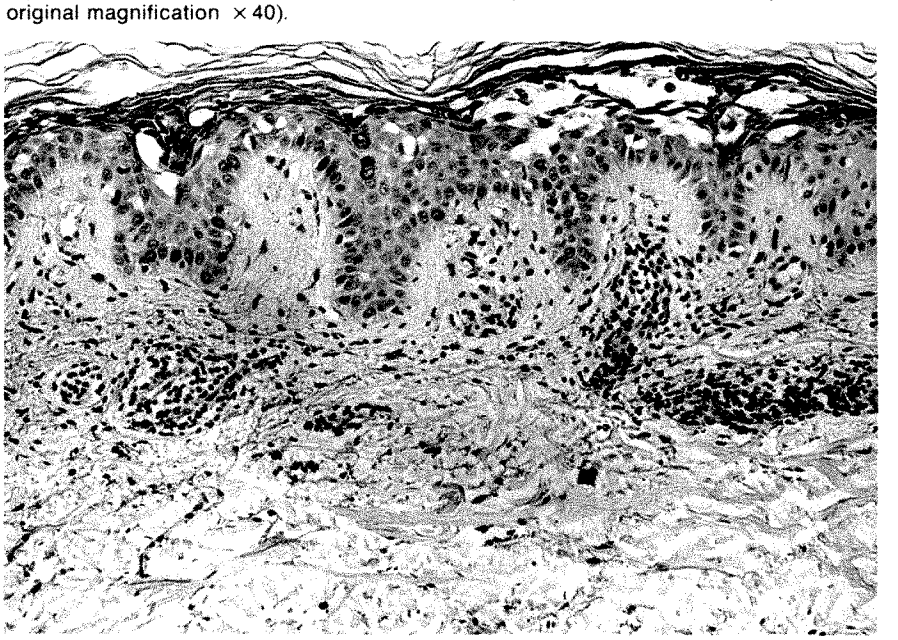

A second histologic pattern was similar to that of pemphigus vulgaris (Fig 5 and 6). There were focal suprabasal clefts, but little overlying acantholysis and no associated dyskeratosis. This pemphigus vulgaris-like change was an isolated finding in 11 cases and was seen in combination with other histologic changes in 12 cases.

A third histologic pattern resembled Hailey-Hailey disease (Fig 7 and 8). In addition to suprabasal clefts, there was abundant acantholysis through the overlying spinous layer. This pattern was found alone in only two cases, but was seen in combination with other histologic changes in three cases. Occasionally, acantholysis was seen only in the upper portion of the epidermis, thus resembling pemphigus foliaceous (Fig 9 and 10). These changes occurred in two of our cases and have also been reported elsewhere.

The fourth histologic pattern was basically spongiotic. Acantholytic cells were present within the spongiotic foci (Fig 11 and 12). Often there was slight intracellular edema in addition to the spongiosis and acantholysis. This spongiotic-acantholytic pattern was seen alone in only two cases, but was the pattern most frequently seen in combination with the other histologic patterns. In nine instances, the spongiotic-acantholytic changes were contiguous to pemphigus vulgaris-like changes. In three cases they were juxtaposed to Darier-like changes. Other combinations of the histologic patterns of TAD are summarized in the Table.

The changes within the dermis were less varied than those within the epidermis. In all cases there was a lymphohistiocytic infiltrate about the vessels of the superficial plexus. In eight of the cases, eosinophils were present within the infiltrate and were associated with spongiosis in all but one case. The changes in the dermis are summarized in the Table.

COMMENT

Transient acantholytic dermatosis is a common disease.[1] One should be alert to the possibility of the diagnosis in patients who are over 40 years old

who have pruritic papular or papulovesicular lesions of the trunk, especially if the pruritus is out of proportion to the apparent clinical disease.

The inordinate persistence of the disease in some patients has cast some shadow on the propriety of characterizing it as "transient." This is especially true of the patient reported by Simon et al,[6] and the group of patients presented by Heaphy et al[8] under the term "benign papular acantholytic dermatosis" but which appears in our opinion, to be TAD. Since the majority of patients with TAD have a brief course and since the patient with persistent disease is the exception rather than the rule, we believe that the allusion to transience is still valid, especially when the disease is compared with the essentially life-long genodermatoses with which it is apt to be confused histologically.

From the pathologist's viewpoint, TAD has diverse histologic patterns with the unifying feature of acantholysis. Acantholysis can appear at any level of the epidermis and can be accompanied by dyskeratosis. Our study indicates that at least four identifiable patterns may be found in transient acantholytic dermatosis: Darier-like, pemphigus vulgaris-like, Hailey-Hailey-like, and spongiotic-acantholytic. These patterns may occur singly or in combination. The variability of the acantholytic phenomenon as expressed in TAD is witnessed in other acantholytic processes, such as pemphigus vulgaris. A single biopsy specimen from a patient with indubitable pemphigus vulgaris may show, in addition to the typical histologic findings of that disease, features of pemphigus foliaceus and Hailey-Hailey disease.

Some cases of TAD are indistinguishable histologically from Darier disease. When the cornified layer has a normal basket-weave pattern or slight parakeratosis rather than prominent focal vertical parakeratosis, or when there is associated spongiosis, the diagnosis is more likely to be TAD rather than Darier disease.

In those forms of TAD that resemble pemphigus vulgaris or Hailey-Hailey disease, a critical point of distinction is the focal nature of the lesion of TAD. In pemphigus vulgaris and Hailey-Hailey disease, the acantholytic change usually occupies the entire breadth of the specimen, whereas the acantholytic changes in TAD are highly circumscribed. This change, of course, is consonant with the clinical pattern of the former two diseases in which a substantial blister is the primary lesion, in contradistinction to the discrete papules and papulovesicles of TAD.

Another clue to the diagnosis of TAD is the association of acantholysis with spongiosis. In our experience, TAD is the only disease in which this association can be noted by light microscopy.

Incidence of Skin Carcinoma After Renal Transplantation

Eugene O. Hoxtell, MD; Jack S. Mandel, MPH;
Samuel S. Murray; Leonard M. Schuman, MD, MS; Robert W. Goltz, MD

• The development of de novo malignant neoplasms after renal transplantation continues to be of importance. The incidence of skin cancer in the renal transplant population at the University of Minnesota Hospital is compared with that expected on the basis of rates from the special nonmelanoma part of the Third National Cancer Survey. Overall, the risk of skin cancer in the renal transplant population was 7.1 times that expected. This excess was due primarily to squamous cell carcinomas, which were 36.4 times as frequent as expected.

(*Arch Dermatol* 113:436-438, 1977)

More than 16,000 patients undergoing kidney transplants have now been registered with the American College of Surgeons/National Institutes of Health Renal Transplant Registry. Of these recipients, 6,781 are still alive with a functioning graft. The development of de novo malignant neoplasms after renal transplantation continues to be of importance.[1] Two types of neoplasms account for most of the malignancies: lymphomas and epidermoid carcinomas. By comparison with cancer registry data, the risk of a renal transplant recipient developing a lymphoma has been calculated to be 35 times that of the normal population.[2] For reticulum cell sarcoma, the incidence was 350 times greater than the normal population.[2] Skin and lip cancers occurred up to four times more often than expected.[2] In the study by Hoover and Fraumeni, the patients that underwent renal transplants were reported to the Human Renal Transplant Registry (American College of Surgeons) from throughout the country. To compute expected values of skin cancers, data from the nonmelanotic skin cancer survey conducted as part of the Third National Cancer Survey (TNCS) were used.[3] Since only four areas of the country were included in the TNCS, it was necessary to compute a range of expected values, using first a low-incidence area of the survey and then a high-incidence area.

This skin cancer survey, which is the most comprehensive to date, was carried out from Sept 1, 1971, to Feb 29, 1972, in four of the nine areas participating in the TNCS. The five-county Minneapolis-St Paul Standard Metropolitan Statistical Area (SMSA) with a population of 1,813,647 (1,763,769 Caucasians) was one of the areas included in this skin cancer survey. Since most patients with skin cancer are seen and treated in physicians' offices and usually are not hospitalized, the ascertainment of cases was accomplished through surveillance of physicians' offices.

This study compares the incidence of nonmelanotic skin cancer in the renal transplant population at the University of Minnesota with that expected on the basis of rates from

the Minneapolis-St Paul component of the nonmelanotic skin cancer survey. It avoids one of the problems experienced by previous studies, namely, the use of inappropriate skin cancer rates to compute expected values for comparison with patients that undergo renal transplants.[2-4]

SUBJECTS AND METHODS

The study population consisted of all patients who had a renal transplant between Jan 1, 1968, and Dec 31, 1974, at the University of Minnesota. All newly diagnosed cutaneous tumors that occurred through September 1975 were ascertained from the renal transplantation registry. Records of each of these patients were examined, and, when possible, the patient was seen and examined.

For analysis, the patients that underwent renal transplants were divided into ten-year age groups separated by sex. The number of person-years of risk was computed. The expected number of skin cancers was obtained by applying the age-sex-specific incidence rates from the special survey of nonmelanotic skin cancers in the Minneapolis-St Paul SMSA.

The expected numbers of skin cancers were summed, and the totals compared with the observed numbers by means of risk ratios (observed/expected). A significance test was applied by comparing the observed number with its expectation under the Poisson assumption.[5]

RESULTS

Seven cases of skin cancer were diagnosed during the study period among the 495 patients that underwent renal transplants. Four of seven (57%) cases were squamous cell carcinomas, whereas in the TNCS data, only 14% of the skin cancers were of this cell type.

Overall, the risk of skin cancer was 7.1 times that expected for both men and women (Table). This excess was due primarily to the squamous cell carcinomas, which were 36.4 times that expected. The risk ratio for basal cell carcinomas was statistically significant ($P < .01$) only for women. We have no explanation for this difference. It is likely that it is secondary to the small number of cases available for study.

The mean age of the seven patients with cutaneous carcinomas was 48 years (range, 35 to 64 years). The mean time from transplantation to diagnosis of first cutaneous carcinoma was 43.4 months (range, 18 to 66 months).

Four of the seven patients had more than one cutaneous carcinoma diagnosed. The seven patients had a total of 17 cutaneous carcinomas: thus, the mean number of carcinomas was 2.43 per patient. In the TNCS, the mean number of lesions was 1.09 carcinomas per patient. Data on the baseline population are not available to do a detailed age- and sex-adjusted comparison of the occurrence of multiple carcinomas. All of the multiple carcinomas were squamous cell carcinomas located on sun-exposed areas of the body. One patient had six squamous cell carcinomas of the head and neck area during an 18 month period. Two other patients had three squamous cell carcinomas each; these also were on sun-exposed areas.

This study confirms the previously reported finding of an increased risk of skin cancer among patients undergoing renal transplants. Rates used to compute expected values can be considered more appropriate than those used in previous studies. In our study, most of the patients that underwent renal transplants were residents of the Minneapolis-St Paul SMSA and the skin cancer survey component of the TNCS was conducted around the midpoint of the study period. Therefore, use of these data to compute expected values avoids some of the potential problems encountered in previous studies.

The relatively small number of observed skin cancers must be considered in interpreting the results. Likewise, the fact that the renal transplant recipients are a closely followed up population must be considered. Nevertheless, the substantial increase in incidence of cutaneous malignant neoplasms observed in this renal transplant population is compatible with previous studies. This finding is also compatible with the increase of malignant neoplasms noted among patients with naturally occurring impairment of immunity, particularly in those with deficiencies of cell-mediated immunity.[6-9] Malignant neoplasms also have been observed in patients not undergoing renal transplants who have received immunosuppressive agents for other therapeutic purposes.[10-13] Included in these groups are several patients with cutaneous carcinomas.

The theory of immunologic surveillance was predicted by Paul Ehrlich in 1908, when he stated, "in the enormously complicated course of fetal and post-fetal development aberrant cells become unusually common. Fortunately in the majority of people they remain completely latent thanks to the organisms' positive mechanisms."[14] Tumor-specific antigens and both humoral and cell-mediated

immunity have been demonstrated in several human neoplasms.[15] Experimental animal studies have also showed that the interference with development of immunologic competency by thymectomy facilitates the development of neoplasms induced by both chemical carcinogens[16] and of neoplasms induced by oncogenic viruses.[17] It has been suggested that in addition to the immunosuppressive agents administered to renal transplant recipients, a further anergy induced by antigen load, namely, the grafted organ, may be of importance.[18]

A number of published reports have discussed de novo cutaneous malignant neoplasms occurring in renal transplant recipients.[13,19-24] From these reports and the present study, a number of conclusions can be drawn. The cutaneous malignant neoplasms occur primarily on sun-exposed areas. The incidence appears to be higher in areas of greater sun exposure. The risk appears to increase with time from transplantation. Multiple carcinomas in the same patient are common, and squamous cell carcinomas outnumber basal cell carcinomas.

Studies leading to this publication were supported in part by funds from Public Health Service training grant T01 AM 05560.

Curettage-Electrodesiccation Treatment of Basal Cell Carcinomas

Alfred W. Kopf, MD; Robert S. Bart, MD; David Schrager; Mark Lazar; George L. Popkin, MD

• Cure rates after treatment of basal cell carcinomas with curettage-electrodesiccation were compared among three groups: group A, 597 lesions treated in the Skin and Cancer Unit in 1958 to 1962; group B, 91 lesions treated in the Skin and Cancer Unit in 1970; and group C, 210 lesions treated in private practice in 1962 to 1973. The following were the five-year cumulative recurrence rates: group A, 18.8%; group B, 9.6%; and group C, 5.7%. In all three groups, there were high recurrence rates for tumors treated on the nose, paranasal areas, and forehead.

Few complications occurred after curettage-electrodesiccation with the exception of hypertrophic scars. The cosmetic results following curettage-electrodesiccation improved with time.

Curettage-electrodesiccation, when performed by experienced physicians, is a very useful modality for the treatment of basal cell carcinomas, with cure rates of over 90%, satisfactory cosmetic results, and few significant complications.

***(Arch Dermatol* 113:439-443, 1977)**

The procedure of curettage-electrodesiccation is the most frequently used method for the treatment of basal cell carcinomas in the Skin and Cancer Unit. Of the 3,033 consecutive, histologically-proved, coded lesions of this type first seen from 1955 to 1967, 51.6% were treated by curettage-electrodesiccation; 25.7% were treated by x-radiation, 17.3% by excision, and 5.4% by other methods.

Some authors have stressed the importance of experience in the technique of curettage-electrodesiccation.[1,2] The present study is a comparison of the results achieved with curettage-electrodesiccation of 688 histologically-verified basal cell carcinomas treated in our clinic with the results in 210 lesions treated in private practice.

Accepted for publication July 26, 1976.

Reprints not available.

MATERIALS AND METHODS

A total of 898 histologically proved basal cell carcinomas treated by curettage-electrodesiccation in the Skin and Cancer Unit and in the private practices of two of the authors were reviewed. There were three groups of lesions as follows: group A, 597 lesions (in 477 patients) coded and treated in the clinic during 1958 to 1962; group B, 91 lesions (in 69 patients) coded and treated in the clinic in 1970; and group C, 210 tumors (in 92 patients) combined from the active files of the private practices of two of the authors (AWK and RSB) treated during 1962 to 1973.

Table 1 shows the number of lesions per patient in each of the three groups. Table 2 summarizes the anatomic locations (head and neck versus trunk and extremities) of the lesions.

Groups A, B, and C were compared for cumulative recurrence rates using a modification of the life-table method of Cutler and Ederer.[3] The value of this method lies in its ability to utilize follow-up information on patients who have been observed for varying lengths of time. When the data were insufficient to employ this method, a raw recurrence rate was determined by dividing the number of recurrences by the total number of lesions treated in that category or subgroup. For raw recurrence rates, all recurrences were included, regardless of when they were discovered. Thus, a recurrence found 15 years after curettage-electrodesiccation would be included in raw recurrence rates but not in the cumulative recurrence rates that were calculated to only five years. Therefore, in group A, 108 recurrences are reflected in calculations of raw recurrence rates, and only 93 in the five-year cumulative recurrence rate (Table 3). Raw recurrence rates were determined for various anatomic sites and lesion sizes. The results of retreating recurrences with various modalities were analyzed.

RESULTS

Comparison Between Clinic and Private Patient Groups

Table 1 shows that in this study there was a much lower percentage of lesions from clinic patients with multiple basal cell carcinomas (group A, 34.2%; group B, 27.5%) as compared to the percentage of lesions from private patients with multiple basal cell carcinomas (group C, 77.1%). Furthermore, as shown in Table 2, there was a substantially lower percentage of treated lesions on the trunk and extremities in the clinic patients (group A, 17%; group B, 33%) than in the private patients (group C, 48%).

Recurrences

Table 3 shows the cumulative recurrence rates for the clinic groups for the first five years of follow-up. The five-year cumulative recurrence rate for group A was 18.8% and that for group B was 9.6%. Table 3 also shows the five-year cumulative recurrence rate for the private-practice group which was 5.7%.

Table 4 compares the raw recurrence rates of tumors grouped according to their largest diameters. There is a general trend toward increasing recurrence rates with in-

creasing tumor diameters; however, there were no recurrences in the private practice group for lesions over 20 mm in diameter.

Table 5 shows the raw recurrence rates for lesions on the forehead, cheek, nasal-paranasal, and trunk extremity areas as compared to all other areas. In all three groups, recurrence rates were high on the forehead (group A, 20.5%; group B, 18.2%; group C, 12.5%), and low on the trunk and extremities (group A, 8.8%; group B, 3.3%; group C, 2.0%). On the other anatomic sites, the recurrence rates varied widely among the three groups.

Retreatment of Recurrences

Table 6 outlines how the recurrences in group A (clinic, 1958 to 1962) were retreated and the results at final examination. These data can be summarized as follows:

1. Out of 597 lesions, there were 108 recurrences (18.1% raw rate).
2. Of the 57 lesions where curettage-electrodesiccation was the meth-

*Number of lesions at start of previous year less those lost (b) and less those which recurred (e) in previous year.
†Total years of exposure of those lost in period computed to the fraction of the year followed.
‡Rate of no recurrence (g) times cumulative rate of no recurrence in the previous year (h).
§Standard error = ±0.0179 (group 1); ±0.0376 (group 2); and ±0.0214 (group 3).[3]

od of retreatment, 28 (49%) recurred at least once more.

3. Of the 20 lesions where surgical excision was the method of retreatment, four (20%) recurred at least once more.

4. Of the 18 lesions where x-ray therapy was the method of retreatment, two (11%) recurred at least once more.

5. Of the five lesions where chemosurgery was the method of retreatment, no second recurrences were observed.

6. The overall incidence of second recurrences was 34.0% (35 out of 103 lesions).

7. Of the 28 second recurrences following curettage-electrodesiccation, 21 were eventually cured and 7 had tumor at the time of last examination.

8. Of the four second recurrences following excision, two were eventually cured, and two had tumor at the time of last examination.

9. Of the two second recurrences following x-ray treatment, one was eventually cured and the other had tumor at the time of last examination.

10. The overall eventual cure rate (no recurrence at last observation) of the 103 recurrent basal cell carcinomas was 89.3%.

Of the 597 lesions that were followed after definitive treatment of the original tumor, or of their recurrences, only 16 (including the 5 lost to follow-up) had tumor present at the last examination. Thus, at last observation, 97.3% of the lesions showed no evidence of recurrence.

Cosmetic Results After Treatment of Nonrecurrent Lesions in Group A

The cosmetic appearance of the treated site is evaluated at the time of each return visit to the clinic and designated as excellent, good, fair, or poor. When the treated area cannot be easily distinguished from the surrounding untreated skin, the result is considered "excellent." A "poor" result is an unsightly alteration of the skin. "Fair" and "good" refer to results that are intermediate between these extremes. The cosmetic results used for analysis were the ones recorded at the time of last examination. Table 7 reveals that cosmetic results tend to improve with time. Excellent or good cosmetic results were observed in 47% of the lesions within the 1st year of treatments, in 78% in the 3rd year after treatment, and in 83% in the 10th to 15th years.

Sequelae and Complications in Group A

The wound produced by the curettage-electrodesiccation procedure heals by secondary intention and results in scarring of varying degree. The commonest complication following curettage-electrodesiccation is a thickened scar, which occurred in 98 of the 597 treatment sites (Table 8). The distinction between hypertrophic scar and keloid is a matter of clinical judgment. In a true keloid, the exuberant scarring spreads beyond the area treated and usually persists indefi-

nitely whereas hypertrophic scars are confined to the treated area and often involute spontaneously in a year or so.

Other complications were much less frequent and included hypopigmentation, atrophy, and persistent erythema.

COMMENT

One is struck by the very high five-year recurrence rate (18.8%) of basal cell carcinomas treated by curettage-electrodesiccation in group A (clinic: 1958 to 1962) compared to that (5.7%) seen in group C (private practice). The recurrence rate in group B (clinic: 1970) was intermediate (9.6%). Previously published series have reported recurrence rates ranging from a high of 12.3%[1] to a low of 2.5%[5] with the technique of curettage-electrodesiccation (see Table 9).

There are several plausible explanations for the marked difference in the recurrence rates between group A (clinic patients) and group C (private patients). The first is the selection of lesions. In the oncology section of the clinic, physicians code only one or a few lesions if the patient has numerous basal cell carcinomas. Therefore, the less impressive lesions may not enter into the statistics, and the bias is toward inclusion of the more difficult-to-cure tumors. In comparison, group C included all basal cell carcinomas in the active files of the two private practices.

Another possible factor contribut-

Group B (clinic: 1970)	91	5	9.6
Group C (private patients)	210	5	5.7

*"X" and "Y" refer to two attending physicians who treated patients with curettage-electrodesiccation by slightly different techniques.

ing to the higher recurrence rates in the clinic groups is the lesser experience of the physicians in training. Jackson[1] and Williamson and Jackson[2] reported that the recurrence rates of lesions treated by residents were significantly lowered as a result of greater supervision, approaching the lower recurrence rates achieved by the attendings. In the late 1960s, after preliminary data showed a high recurrence rate in our clinic, steps were taken to improve the supervision and training of resident physicians doing the curettage-electrodesiccation procedures. Analogous to the experience of Jackson, the recurrence rate was significantly lowered in group B (ie, lesions treated in 1970) in comparison group A (ie, lesions treated in the clinic in years 1958 to 1962).

An additional explanation for the higher recurrence rate in the clinic groups is the higher percentage of head and neck lesions compared to the private practice group. Undoubtedly, there is a natural tendency to give greater consideration to cosmetic results when treating lesions on the face and therefore to be less vigorous in the treatment procedure.

The improvement of cosmetic results with time following curettage-electrodesiccation is in accord with previous studies[1,4,6-11] and is in contrast to the deterioration in cosmetic results which was seen in our study on the treatment of basal cell carcinomas with x-rays.[12] Following curettage-electrodesiccation, excellent to good cosmetic results were observed in 47% of lesions during the 1st year of follow-up; in 78% in the 3rd year; and 83% in the 10th to 15th years. In contrast, the figures for our series of 500 x-ray-treated basal cell carcinomas were 73.6% in the 1st year; 67% in the 3rd and 4th years, and 48.6% in the 9th to 13th years. These differences are primarily due to the progressive radiodermatitis resulting from cancericidal doses of x-rays.

Hypertrophic scars were the most common complication of curettage-electrodesiccation treatment of basal cell carcinomas. Fortunately, they usually involuted spontaneously. In contrast, hypertrophic scars were very rare after x-ray treatment. Papule or nodule formations, verrucous lesions, and ulcers, the most common complications after x-ray therapy, were not seen in our patients who had been treated by curettage-electrodesiccation.

The pattern of second recurrences of basal cell carcinomas originally treated by curettage-electrodesiccation is similar to that reported by Menn et al,[13] but shows generally lower rates of second recurrences. The pattern is the same in that in descending order of magnitude the treatments showing the highest second recurrence rates of lesions originally treated by curettage-electrodesiccation are as follows: curettage-electrodesiccation, surgical excision, x-ray treatment, and Mohs' surgery. Menn et al[13] observed an overall second recurrence rate of 49.2% (31 of 63 lesions following retreatment), whereas the present study indicates the somewhat lower rate of 34.0% (35 of our 103 lesions). Our results once again indicate that recurrent lesions must be treated more aggressively than previously untreated lesions. It also suggests that Mohs' surgery is probably the treatment of choice for recurrent lesions. According to a communication in March 1976, Mohs achieved a 96.8% five-year cure-rate treating 1,387 consecutive recurrent basal cell carcinomas with chemosurgery. In a series of 214 recurrent basal cell carcinomas treated in the Chemosurgery Section of the Skin and Cancer Unit, the three-year cure rate was 96.3%.[14]

The cumulative recurrence rates (9.6% and 18.8%) reported here for clinic lesions are greater than the rate (7.9%) reported for our series of 500 basal cell carcinomas treated in our clinic by a standardized x-ray method.[12] It should be emphasized, however, that highly experienced personnel were directly involved in the therapy of all the basal cell carcinomas treated with x-rays. Although the general principles of curettage-electrodesiccation are well established, there is considerable variation in technique and no one "standardized" method is followed by all practitioners. This is in marked contrast to our study on x-ray therapy of basal cell carcinomas where a uniform "standardized" method of treatment was employed.[12]

Future studies should attempt to identify those elements of the curettage-electrodesiccation technique that result in the highest cure rates, fewest complications, and best cosmetic results. Possibly, a more standardized technique of curettage-electrodesiccation for the treatment of basal cell carcinomas of the skin could be defined and taught in graduate training programs.

Acne Fulminans

Investigation of Acute Febrile Ulcerative Acne

Herbert Goldschmidt, MD; James J. Leyden, MD; Kenneth H. Stein, MD

• Eight cases of acne fulminans (acute febrile ulcerative acne) are compared with 13 previously reported cases. This rare disorder of male teenage patients is characterized by the sudden appearance of highly inflammatory, tender, ulcerative and crusted lesions on the back, chest, and face: it is one of the most scarring acute dermatologic disorders of young patients. At the onset of the disease, all patients showed febrile temperatures and marked leukocytosis; other systemic symptoms occurred with varying frequency. Polyarthralgia was noted in half of our series.

Investigations of potential trigger mechanisms (eg, septisemia due to *Corynebacterium acnes*, immunologic defects, altered polymorphonuclear leukocyte function, Shwartzman phenomenon) did not yield any clues regarding the pathogenesis of this disease. Clinical and laboratory findings suggest that acne fulminans is not directly related to acne conglobata.

(*Arch Dermatol* 113:444-449, 1977)

Eight new cases of acne fulminans (acute febrile ulcerative acne) are compared with 13 previously reported cases. This rare disorder of male teenage patients is characterized by the sudden appearance of highly inflammatory, tender, ulcerative, and crusted lesions on back, chest and face; it is one of the most scarring acute dermatologic disorders of young patients. At the onset of the disease, all patients showed febrile temperatures and marked leukocytosis; other systemic symptoms occurred with varying frequency. Polyarthralgia was noted in one half of our series.

Accepted for publication July 29, 1976.

From the Department of Dermatology, University of Pennsylvania Medical School, Philadelphia.

Reprints not available.

Investigations of potential trigger mechanisms (eg, septicemia due to *Corynebacterium acnes*, immunologic defects, altered polymorphonuclear leukocyte function, Shwartzman phenomenon) did not yield any clues regarding the etiology and pathogenesis of this disease. Clinical, histological, and laboratory findings suggest that acne fulminans is not directly related to acne conglobata.

REPORT OF CASES

Eight patients with acne fulminans were observed in the private office of one of us (H.G.) and at the Hospital of the University of Pennsylvania. A summary of pertinent findings is presented in Table 1 (cases 14 to 21). Due to space limitations only one characteristic case can be described in detail.

CASE 14.—This 13-year-old boy gave a history of severe acne of six months' duration. The eruption started with suddenly developing multiple pustular lesions on his shoulders that spread to involve his face, back, and chest. For the six weeks prior to admission, progression of the eruption continued and the lesions became markedly tender. Febrile episodes up to 38.3C (101F), weight loss of 5.4 kg, back pain, and extreme malaise were additional symptoms. A trial of tetracycline, 1 gm daily for four weeks, in addition to intensive topical treatment were without effect on the lesions. He had no past history of gastrointestinal symptoms or of recurrent infections. An older sister had comedonal acne as a teenager that has subsequently resolved. The patient has a history of seborrheic dermatitis and hayfever in the spring.

Physical Examination.—On admission the physical examination revealed a young man in some distress. Temperature was 37.8C (100F); pulse rate, 100 beats per minute; blood pressure, 110/70 mm Hg. Tender and crusted ulcerated lesions covered with hemorrhagic exudate were distributed on his back (Fig 1), anterior part of the chest, shoulders, and the proximal portions of his upper extremities (Fig 2). Multiple discrete pustular lesions on an erythematous base involved the same areas. Few comedones were seen and the face was relatively spared. Early atrophic scars were seen on back and chest.

The patient showed progressive resolution of his active lesions and marked symptomatic improvement within five days on a regimen of cephalexin monohydrate (Keflex) 1 gm daily, and prednisone, 40 mg daily. Supplemental therapy consisted of Burow's compresses every two hours to the involved areas. Milk, milk products, and iodides were restricted in his diet. At the time of discharge two weeks later there were no active lesions. The prednisone was tapered off slowly over the next four weeks.

Laboratory Data.—The hemoglobin level was 15 gm/100 ml, hematocrit reading was 47%, and the red cell count was 5.4×10^6. Platelets were adequate. The white count was 18,000 with 75% neutrophils, 20% lymphocytes, and 5% monocytes. Results of blood glucose, blood urea nitrogen, serum electrolytes, urinalysis, T-4 uptake, rapid plasma reagin card test, and electrocardiogram were normal. The sedimentation rate was 43 mm/hr (Wintrobe). Chest x-ray films, barium enema, and upper gastrointestinal series were normal.

Intradermal antigenic skin tests to *Streptococcus faecalis*, *S pyogenes*, *S nonhemolyticus*, *Staphylococcus aureus*, *Micrococcus*, *Proteus vulgaris*, *pseudomonas*, oidiomycin, trichophytin, and intermediate purified protein derivative (PPD) were negative. The mumps intradermal skin test was positive. Serum protein electrophoresis revealed a small increase in the α_1-globulin, an increase in the α_2-globulin fraction to 1.21 gm (normal, 0.34 to 0.7), and an increase in the β-globulin to 1.14 gm (normal, 0.52 to 0.94). Immunoelectrophoresis showed that all immunoglobulin bands were smooth and without distortion. There was no evidence of a paraprotein. Quantitative immunoglobulin surveys revealed normal levels of IgG, IgA, and IgM. A lumbosacral film revealed spondylolisthesis of

the L-4 and L-5 vertebral level.

Assays of neutrophil mobilization, phagocytic and chemotactic activity, and random mobility of the neutrophils showed no abnormality.

Cultures of pustular lesions revealed micrococci and *C acnes*. Blood cultures were negative. Several biopsies were taken that revealed severe inflammatory changes.

REVIEW AND SUMMARY OF PUBLISHED CASES

A review of the world literature revealed 13 published cases of acne fulminans.[1-3] The essential data are presented in Table 1 that also includes our own eight cases. All patients were white male teenagers, the majority with a history of only mild preceding acne vulgaris. Their ages at the onset of the disease ranged from 13 to 19 years (with a median age of 16); few patients continued into their 20s. All patients had acute sudden onset of severe painful ulcerative cutaneous lesions and systemic symptoms. Thirteen of 21 patients had arthralgia of varying degree; 8 had no joint symptoms. All patients had elevated temperatures, ranging from 101 to 103° with a median temperature of 101.5. The WBC was markedly elevated from 10,000 to 33,000 with a median elevation of 16,000 leukocytes. The sedimentation rate was raised from 37 to 145/hr with a median elevation of 84/hr. All other symptoms varied considerably.

COMMENT

Clinical Findings

The clinical findings of the presented eight new cases correspond

Fig 3.—Case 18. Widespread large ulcerative lesions with hemorrhagic crusts, early pustular lesions, and scarring.

Fig 4.—Case 18. Same patient three months later. Lesions have healed with marked atrophic and hypertrophic erythematous scars.

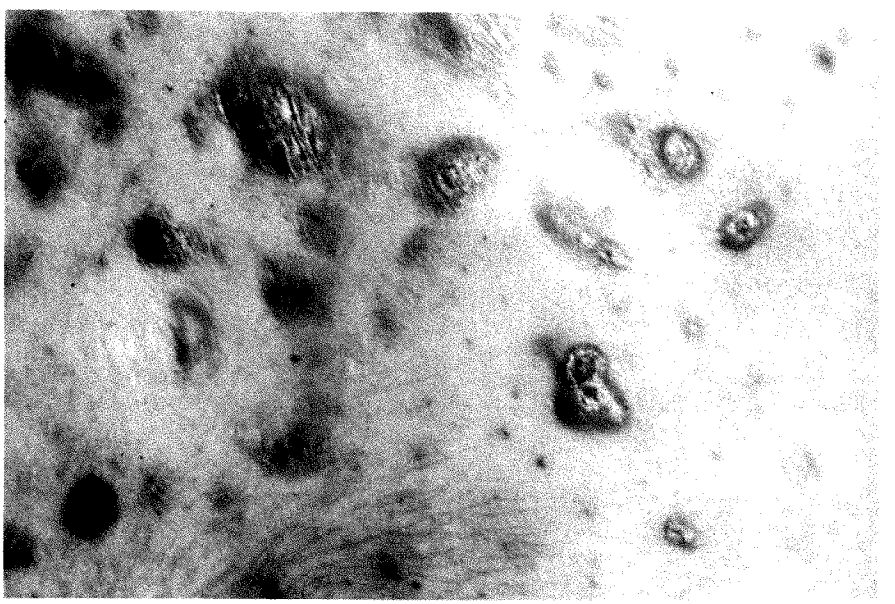

Fig 5.—Case 17. Close-up view of sternal region showing numerous small pustular lesions with inflammatory halos, nodules, early erythematous ulcers, and atrophic scarring.

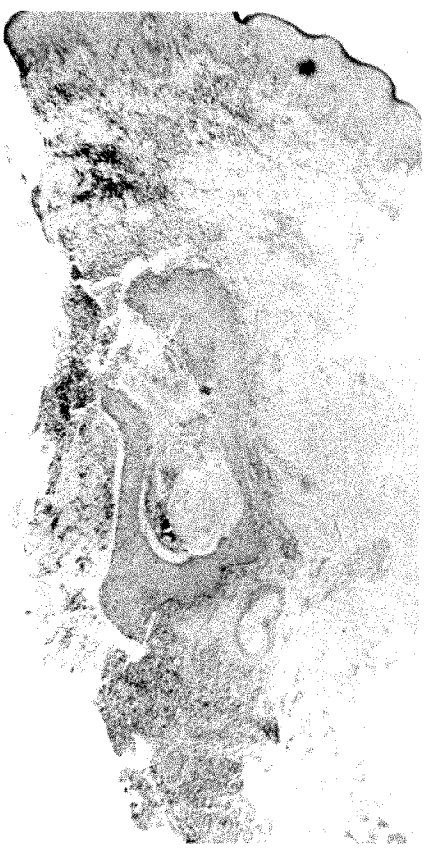

Fig 6.—Pustule showing ruptured follicular wall, intrafollicular accumulation of keratinous material, and intense infiltrate composed mostly of polymorphonuclear neutrophils.

closely to the previously published cases.[1-6] Our eight patients were young men (13 to 19 years old) who had only mild to moderate acne of the facial (and back) area for one to two years prior to the onset of the widespread acute eruption. The predilection areas were the shoulders, upper part of the back, and upper part of the chest (Fig 1-4); characteristically, the anterior and lateral neck region (including a 5 to 10 cm semicircular area of adjacent skin) and the lateral trunk below and including the axillary region were completely clear in most patients (Fig 2). The facial area was either not involved or showed only mild to moderate acne lesions.

In very early stages, small 2 to 3 mm pustules on an erythematous base could be discerned as primary lesions (Fig 5). They rapidly developed into large 1 to 5 cm sized, discrete or confluent dark, oval or round, slightly raised erythematous lesions with a thin friable surface layer that could be easily removed by moderate tangential pressure revealing a gelatinous reddish-yellow ulceration. Many of these ulcerative lesions were covered with thick hemorrhagic crusts. Nodular or cystic lesions were seen only rarely. The number and size of comedones was also inconspicuous; large polyporous (double or triple) come-

Fig 7.—Ulcerative lesion showing denuded epidermis, intense infiltrate of polymophonuclear neutrophils, and occasional remnants of follicular epithelium and sebaceous glands.

Fig 8.—Later fluctuant, nodular lesion with regenerated, acanthotic epidermis, persistent dense inflammatory infiltrate, dermal edema, and numerous dilated vessels.

dones were not observed. Both the small and large lesions were extremely tender causing the patient to walk or stand with his neck bent and his shoulders drooping. This characteristic gait and posture often gave a diagnostic clue even at a distance.

Systemic symptoms were present in all eight patients, particularly fever, chills, and malaise during the acute stage. Polyarthralgia was reported in varying degrees by four of our patients; the remaining four denied joint pain. Weight loss (often more than 4.5 kg in two to three months) occurred in the majority of our patients.

Laboratory Findings

All patients had a leukocytosis of more than 12,000 with polymorphonuclear leukocytes. Where done, the ESR was elevated more than 40 mm/hr. Anemia was not a consistent finding.

The results of multiple cultures taken from early and late lesions and from the nasal mucosa were inconclusive. The *C acnes* and micrococci were frequently demonstrated in varying numbers, and *St aureus* was found only in rare instances. *Proteus* was cultured from only one of three lesions of one patient. A particular bacteriological pattern could not be established. Repeated special blood cultures were also started in three patients but failed to reveal any evidence of septicemia due to aerobic or anaerobic microorganisms (eg, due to *C acnes*). Results of various other routine laboratory studies were also normal. In particular, we were unable to find any indication for an immunological defect. Intradermal skin tests with bacterial and other antigens showed normal responses. Results of serum protein electrophoresis were either normal or showed a small increase in α_1-globulin, α_2-globulin, and M globulin. Immunoelectrophoresis showed that all bands were smooth and without distortion. Quantitative immunoglobulin surveys revealed normal levels of IgG, IgA, and IgM. Assays of neutrophil mobilization, phagocytosis, chemotaxis, and random mobility of neutrophiles were normal. Skin tests with a suspension of the patient's comedones (heat-killed and control) were done in one patient and did not show any difference in reaction in a dilution of 1:100.

Histology

Since previous reports lack detailed data on microscopic findings, various stages of acne fulminans were examined histologically.

Early Pustular Lesions.—The early pustular lesions showed an intense infiltrate consisting of polymorphonuclear cells and some histiocytes with invasion and destruction of the follicular wall (Fig 6). Some follicles showed some distension with accumulated keratinized cells (microcomedone formation) but others did not reveal any tendency for comedone formation. The polymophonuclear infiltrate often extended down to the panniculus (Fig 6). Clinically such lesions showed an intense erythema surrounding the pustule.

Ulcerative and Nodular Lesions.—Many lesions showed a thick hemorrhagic crust; the epidermis showed extensive necrosis or was entirely missing. In the dermis there was an intense, deep infiltrate comprised of polymorphonuclear neutrophiles, histiocytes, and lymphocytes (Fig 7 and 8). Follicular structures were absent except for occasional follicular remnants. Several lesions showed extensive edema and vascular hyperplasia deep in the dermis (Fig 7). In all cases the infiltrate was predominantly perivascular; occasional invasion of blood vessel walls was seen but nuclear dust, fibrinoid material, or endothelial changes were not noted. A late lesion showed a regenerated acanthotic epidermis with the dermis containing a dense mixed cellular infiltrate, vascular hyperplasia, and numerous stellate fibroblastic cells.

Normal Skin.—Biopsies of normal skin areas of the back of three patients showed no abnormalities.

Summary of Microscopic Findings

The histologic findings could be interpreted as a markedly exaggerated fulminant follicular reaction developing into an extensive, spreading, liquefying necrosis engulfing neighboring follicles in its path. (In contrast, in mild to moderate acne vulgaris ruptured microcomedones result only in relatively small and limited perifollicular abscesses.) No evidence of vasculitis or other changes

Table 2.—Differential Diagnosis of Acne Fulminans*

	Acne Vulgaris	Acne Conglobata	Tropical Acne	Acne Fulminans
Cutaneous Signs

Systemic steroids	+ − + +	+ − + +	− (without climatic change)	+ +

*Explanation: − = Not seen; + = rare; + + = common; + + + = very common.

suggestive of an immune or Shwartzman type reaction were detected. The paucity of clinically visible comedones could be explained by the fulminant course of this disease that does not allow for sufficient time to develop visible comedones from subclinical microcomedones.

Therapeutic Results

Most of our patients gave a history of unsatisfactory responses to routine acne treatments, often extending over six to eight months prior to the initiation of intensive and proper therapy.

The majority of these patients responded dramatically to a combination of systemic steroids (eg, prednisone 30 mg daily in gradually decreasing dosage) with systemic antibiotics over a period of six to eight weeks. Tetracycline (500 mg, three times a day), demeclocycline hydrochloride (Declomycin) (300 mg, twice a day), clindamycin (Cleocin) (150 mg, three times a day), and cephalexin monohydrate (500 mg, three times a day) were ineffective without concomitant systemic steroid therapy but seemed to be helpful as supportive antibacterial treatment. Because of the severity of symptoms no attempt was made in this series of patients to determine if treatment with corticosteroids without antibiotics could be equally effective.

In contrast to other reported cases only three of our eight cases showed a tendency to chronicity and repeated exacerbations after six months with proper therapy (including corticosteroids). The other five of eight patients were free of symptoms; only the preexisting mild or moderate involvement with acne vulgaris continued to a certain degree after the acute eruption had cleared up. The therapeutic efficacy of sulfone therapy could not be properly evaluated because of our limited number of cases. Dapsone (Avlosulfon) (100 to 200 mg daily) was used in two patients but had to be discontinued in one patient because of possibly related side effects. In the early stages of our investigation (when we were unaware of the need for higher doses of systemic steroids) two patients with severe scarring lesions were recalcitrant to all systemic regimens (including antibiotics and 10 to 15 mg of prednisone) or topical therapy (including sulfurated lime solution [Vleminckx solution] and various steroid and antibiotic creams). They were eventually treated with cautious dermatologic radiotherapy, using a half-value layer of 0.9 mm Al with a half-value depth of 12 mm of skin, with weekly doses of 80 R up to a total of 720 R to the upper part of the back and chest with careful shielding on noninvolved areas, eyes, thyroid, and gonads. Response to ionizing radiation in these two patients was extremely satisfactory and even three years after radioactive therapy, recurrences have not been observed. Only one of the eight patients is still under treatment for recurrent febrile flares more than two years after his original sudden outbreak.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of this rare and devastating skin condition is still a mystery. Various potential trigger mechanisms were investigated without success. The systemic findings of fever, leukocytosis, increased sedimentation rate, anemia, malaise, and weight loss are suggestive of a septicemia (eg, due to *C acnes*), but repeated careful blood cultures remained negative. Bacteriologic examination showed no unusual flora, with *C acnes* and micrococci prevailing. An immunological deficiency or a generalized hypersensitivity state were also suspected but no specific clues could be found in qualitative or quantitative immunoglobulin assays, skin tests, biopsies, and other studies. It is known that some patients with severe acne conglobata show depressed delayed sensitivity reactions but this could be explained on a nonspecific response to severe inflammatory disease.[7] Extensive assays of neutrophil function were also completely negative. Neutrophil mobilization, phagocytic and chemotactic reactions, and random mobility of neutrophils were normal.

Some authors have suspected a reaction similar to a Shwartzman phenomenon but no evidence could be found for this theory either.

NOSOLOGY

The lack of an internationally accepted scheme for classifying acne and acneiform eruptions has been a primary source of confusion and controversy. This is particularly true for the nosological relations between acne vulgaris with nodular and cystic lesions, acne conglobata, and tropical acne. The mounting number of case reports on acne fulminans further adds to this confusion.

The new classification by Plewig and Kligman[7] seems best suited to clarify this situation. The authors differentiate three main types of acne vulgaris, comedonal acne, papulopustular acne, and acne conglobata. Acute febrile ulcerative acne is mentioned as another variety of acne vulgaris (and not as a subspecies of acne conglobata). When we discussed these patients with Dr Kligman several years ago, he proposed to replace this cumbersome term with "acne fulminans" (from L. fulmen, n. = lightning) that emphasizes the characteristic sudden onset and severity of this disease and avoids reference to acne conglobata that takes a different course and can be distinguished by its different symptomatology and prognosis. This new term has now been adopted in Plewig and Kligman's classification. The shorter term has the added advantage that it does not prejudice further investigations by including in its title symptoms that are completely variable (eg, polyarthralgia) or variable in degree (eg, leukemoid reaction).

DIFFERENTIAL DIAGNOSIS

Table 2 compares acne vulgaris, acne conglobata, tropical acne, and acne fulminans, four potentially scarring varieties of acne involving chest and back, with or without involvement of the facial region.

The clinical and laboratory findings of *acne fulminans* are described above. This rare, severely scarring disease is, in our opinion, a unique and distinct disease that is not directly related to any of the other three diseases. It differs from all other disorders by its sudden, violent onset and the presence of fever and leukocytosis, often also polyarthralgia, malaise, anemia, weight loss, and other systemic findings. Additional unique features are the characteristic ulcerative and crusted lesions that are often equisitely tender. Back and chest are usually more severely involved than the facial area; the neck area is often spared out in a peculiar fashion.

In contrast to acne conglobata, large noninflamed secondary cysts and polyporous (double or triple) comedones are absent. The age distribution (13 to 20 years) most closely resembles acne vulgaris. All published cases have been male patients (a 14-year-old girl was described by Ström et al[6] but was not included in Table 1 because distinctive ulcerative lesions were missing).

Tropical acne[8-10] may resemble acne fulminans closely but its distribution pattern is often different (buttocks, axillae). Various types of severe inflammatory acne lesions are usually present and ulcerative lesions are rare. Tropical acne can easily be ruled out in nontropical climates. Acne fulminans also differs from other diseases by its lack of response to antibiotic therapy and its favorable response to systemic corticosteroids. Presumably, the untreated patient eventually improves when the disease has "burned out" since the marked scarring is unsuitable for further inflammatory flares.

This investigation was supported by the Wende Fund and the Kline Fund.

Herbert B. Allen, MD; Chalmers E. Cornelius, MD; Walter B. Shelley, MD; and Maurice Thew, MD, permitted inclusion of their patients in this study.

Edward Glifort prepared the photographs.

Leukocyte function was investigated in the laboratory of Michael E. Miller, MD.

Host-Defense Mechanisms in Hidradenitis Suppurativa

Vera C. Dvorak, MD; Richard K. Root, MD; Rob Roy MacGregor, MD

• **Host-defense mechanisms were studied in seven patients with active hidradenitis suppurativa (HS). Granulocyte phagocytic function was measured by ingestion of *Staphylococcus aureus* labeled with radioactive carbon 14 and intracellular killing was determined by bactericidal pour plate method. Chemotaxis was measured by radioactive counting of sodium chromate Cr 51 granulocytes migrating in modified Boyden chambers. Granulocyte adherence was estimated in vitro by filtering blood samples through nylon fiber columns. Cell-mediated immunity was measured by intradermal delayed hypersensitivity responses to *Candida*, mumps, streptokinase/streptodornase, and purified protein derivative antigens. No abnormality was demonstrated in any granulocyte or cell-mediated immune function tests. Moreover, all patients had normal immunoglobulin levels and elevated total hemolytic complement. Therefore, we conclude that HS is a localized chronic infection of apocrine glands without a generalized defect in host defense.**

(*Arch Dermatol* 113:450-453, 1977)

Hidradenitis suppurativa (HS) is a chronic suppurative process involving the apocrine glands; the onset is usually after puberty. Early lesions resemble furuncles but progress into subcutaneous abscesses that fistulate and develop intercommunicating sinus tracts, resulting in irregular hypertrophic scars. According to the pathologic findings, HS has been divided into acute (AHS) and chronic (CHS) forms; AHS lacks sinus tracts and hypertrophic scarring. *Staphylococcus aureus* is the most frequent organism found in AHS, while CHS has infection secondary to Gram-negative organisms as frequently as it has with *S aureus*.[1]

Infection is probably a secondary pathogenic event of HS and not its cause. This disease has been produced experimentally by the application of adhesive tape to the axilla.[2] Sequential changes in the apocrine glands included keratinous obstruction of the apocrine ducts, dilatation of the ducts, and severe inflammatory changes in the occluded glands as bacteria trapped beneath the obstructing plug induced a granulocytic exudate. Thus, HS can be defined as a bacterial infection of an obstructed apocrine gland.

Treatment with antibiotics alone usually is successful in AHS, while CHS almost always requires surgical therapy.[3] Pathogenesis is uncertain but some factors appear more frequently in the history of patients with HS than in the general population. These include a family history of the disease, poor hygiene, excessively oily skin secretions, obesity, diabetes mellitus, pilonidal cysts, and acne.[1,2,4] Defects in host-defense mechanisms have been suspected but not systematically investigated in patients with HS. To resolve this question we studied cellular, humoral, and granulocyte defenses in seven patients with HS.

POPULATION AND METHODS

Seven patients were included in the study; three men with a mean age of 31 years and four women with a mean age of 43 years. All patients had characteristic lesions of CHS and all had had at least one surgical drainage procedure in the past. At the time of study all patients had suppurating lesions, two requiring surgery (patients 1 and 6). All were examined on only one occasion except patient 6 who was

examined again three weeks after surgery. None had received antibiotics, corticosteroid therapy, or other medication within ten days of the study.

Controls for the investigation consisted of normal laboratory personnel. On the day of the study leukocytes were separated from patients' and controls' heparinized blood samples by sedimentation with 3% dextran in normal saline solution, followed by hypotonic lysis of RBCs.[5] The leukocytes were concentrated by centrifugation at 80 g for seven minutes and washed twice in modified Hank solution. The total granulocyte content of this mixed leukocyte population was counted and the cells were suspended in Hank balanced salt solution to a final granulocyte concentration of 5×10^6/ml.

Table 1.—Patients' Characteristics*

Patient	Age, yr	Sex	HS Distribution	Duration of HS, yr	Underlying Illness
1	26	M	Generalized	7	Pilonidal cyst two yr prior to onset of HS; psoriasis, 3 yr prior
2	39	F	Generalized	15	Mild obesity; recurrent thrombophlebitis; positive family history for HS
3	30	M	Generalized	10	Four pilonidal cysts prior to onset of HS; acne
4	32	F	Axilla	17	Obesity; adult onset of diabetes mellitus; hypercholesterolemia; pilonidal cyst two yr after onset of HS
5	48	F	Axilla	8	Obesity
6	27	M	Generalized	10	Down syndrome
7	33	F	Generalized	5	Obesity, alcoholism; abnormal glucose tolerance test; positive famly history for HS (sister of patient 2)

*Hidradenitis suppurativa indicated by HS.

Granulocyte Function Studies

Phagocytosis was studied by using *S aureus* 502A labeled with radioactive carbon C 14 as the particle.[6] Bacteria-to-cell ratio was 500:1. The mixture of patient or control leukocytes, labeled bacteria, and autologous serum was incubated at 37 C without aggitation. At successive intervals, ingestion of bacteria was stopped by addition of cold 0.01M sodium flouride. Noningested bacteria were separated from the leukocytes by low-speed centrifugation. Cell pellets were dried overnight and digested with 0.2N sodium hydroxide at 56 C for three hours. The lysate was brought to neutral pH and 1-ml portions were counted in a liquid scintillation counter. The percent uptake of radioactive-labeled bacteria by granulocytes was determined at 8 and 20 minutes of incubation.

Bactericidal ability of granulocytes was determined by a modification of a method developed in this laboratory.[6] A 1:10 ratio of *S aureus* 502A and granulocytes were tumbled in 1 ml of 10% autologous serum and Hank balanced salt solution at 37 C. At 20 minutes, lysostaphin was added to all tubes to kill extracellular bacteria. The incubation was continued and either 10-μl or 100-μl Eppendorf micropippets were used to sample each tube at 20, 30, and 60 minutes. Each sample was placed in 10 ml of distilled water for ten minutes to lyse the granulocytes and 10-μl and 100-μl samples then were mixed into trypticase soy agar pour plates and incubated at 37 C for quantitation of viable bacteria. A cell-free control was plated at 0 and 60 minutes to assure that only cell-associated killing of bacteria was taking place. Bactericidal activity is defined as the percent of ingested bacteria (those present at 20 minutes, after lysostaphin addition to kill extracellular bacteria) that have been killed by 30 and 60 minutes of incubation.

Chemotaxis was measured by a radioactive counting technique in modified Boyden chambers.[7] Chemotactic factor was generated from human serum by activation with endotoxin. *Escherichia coli* 0127:B8 lipopolysaccharide B endotoxin was prepared in normal saline solution at 300 μg/ml and stored at −70 C. For chemotactic factor generation, 0.1 ml of endotoxin solution was mixed with 0.1 ml of the test serum and 0.8 ml of barbital (Veronal) gelatin buffer. This was incubated for 60 minutes at 37 C, after which residual complement was inactivated by heating at 56 C for 30 minutes.[7] Normal chemotaxis was defined as that amount seen when normal control cells were stimulated by the chemotactic factor generated from their own serum. The chemotactic factor generated from patient serum was compared to that from normal serum by the relative chemotactic response of normal cells to each. Chemotaxis of patient and normal cells was measured to those factors from both normal and patient sera.

Granulocyte adherence was estimated in vitro by filtering heparinized whole blood through nylon fiber columns and measuring the number of granulocytes remaining in the column.[8] The 80-mg columns were used for men and 70-mg columns for women.

Cell-Mediated Immune Studies

Delayed hypersensitivity to *Candida*, mumps, streptokinase/streptodornase, and purified protein derivative antigens was tested by measuring the millimeters of induration 48 hours following intracutaneous injection of 0.1 ml of the antigen into the volar surface of the forearm. Induration of more than 5 mm in diameter was considered a positive reaction. Each patient received all four antigens, two to each forearm.

Humoral Immune Studies

Quantitative immunoglobulin levels were measured by radial diffusion on agar plates. Total hemolytic complement was measured by the technique of Kabat and Mayer.[9]

RESULTS

Five patients had chronic, generalized HS and two chronic, localized HS (Table 1). Three patients had a history of pilonidal cysts, which had preceded the onset of HS in two. All women were moderately obese. One had an abnormal glucose tolerance test result and one was overtly diabetic. One patient had Down syndrome and one had active psoriasis. Two of the study subjects were sisters (patients 2 and 7); the daughter of one sister gave a history of bilateral axillary furunculosis on two occasions.

The rates of phagocytosis of *S aureus* 502A after 20 minutes of incubation were not substantially different between the patients and controls (Table 2).

The bactericidal results are expressed in two ways: (1) by a calculation of intracellular killing at 30 and 60 minutes as the percent of bacteria killed after phagocytosis (Table 2) and (2) as the number of bacteria surviving at 20, 30, and 60 minutes of incubation (Table 3). By the first analysis, 96.5% to 99.5% of ingested bacteria were killed at 60 minutes of incuba-

tion in control and patient groups. The second method also showed no difference between controls and patients. Mean granulocyte adherence for women was 73.9% ± 6.1% compared to 70.8% ± 4.3% for normals. The mean value for male patients was 87.2% ± 4.7% vs 76% ± 12.0% for normals (Table 2). All patients produced chemotactic factor that stimulated their own and control granulocytes equally (Table 4), and patient cells showed chemotaxis equal to that of control cells. While the chemotactic factor from the patients produced a greater mean chemotactic response in both normal and patient cells than that from normal controls, the differences were not statistically significant ($P > .1$, Student t test). There was no correlation between chemotactic response and the extent or chronicity of the disease. All of the patients had delayed hypersensitivity reaction to at least one test antigen (Table 2). There was no correlation between the extent of the disease and the size of the induration. All patients had active lesions at the time of study. One patient had mildly elevated IgG and IgA antibody levels and all patients had elevated total hemolytic complement levels.

Two additional patients were studied in 1969 by one of us (RKR). Patient 8 was a 48-year-old man with generalized HS and a history of acne for 30 years. The patient had normal cell-mediated and humoral immunity, as tested by purified protein derivative skin test and immunoglobulin levels. In vivo migration of WBCs to an inflammatory stimulus was evaluated by the Rebuck skin window test,[16] and was normal. Phagocytic values were comparable to those of the control. In the bactericidal assay, *S aureus*, *S albus*, and *E coli* were used as particles; no difference in killing activity was found between the

patient and control for any of these organisms. Patient 9 was a 28-year-old man with HS involving axillae and groins. There was no significant past medical history. No defect in phagocytosis or bacterial killing by granulocytes was found.

COMMENT

A chronic and recurrent infection of the apocrine glands, HS is manifested by draining abscesses. The lack of infections in other sites and good response to surgical excision of apocrine-bearing tissue suggest well-functioning cellular and humoral immune mechanisms in patients with HS; in contrast, patients with primary defects in host immune mechanisms,[6,11] or with underlying diseases resulting in such defects,[12] usually have infections involving multiple sites such as the skin, upper and lower respiratory tracts, and other organs.

Granulocyte response to inflammation involves adherence of granulocytes to endothelium near the stimulus followed by diapedesis into the extravascular space and cell movement in the direction of chemotactic gradients. Phagocytosis and bacterial killing are the last steps in granulocyte response to inflammatory stimuli induced by bacterial infection. Defects occurring in any of these steps can compromise the host's defense against infection.

Chemotaxis, phagocytosis, and intracellular killing of ingested bacteria were normal in all of the patient samples studied. Granulocyte adherence was increased in two patients (1 and 6) and was probably in response to a highly active inflammation. Augmented granulocyte adherence has been described in patients with active inflammation, mediated by a heat-labile plasma factor[13]; on the other hand, anti-inflammatory drugs (aspirin, corticosteroids) inhibit granulocyte adherence.[8] Both patients subsequently required surgical procedures for control of their disease. Total hemolytic complement level was increased in all patients. Complement concentration has been found to increase greatly in inflammatory conditions, as one of the biologic phenomena associated with tissue damage. Elevated complement levels are also found in noninflammatory processes such as myocardial infarction, neoplasms, and thyrotoxicosis.[14] The magnitude of the complement elevation does not appear to correlate with the outcome of the underlying process.

Immunoglobulin levels, as determined by radial diffusion, were normal in all but one of our patients. This patient (patient 6) with Down syndrome had elevated IgG and IgA levels. Patients with Down syndrome and other chromosomal abnormalities have been described as having elevated IgG, IgA, and total γ-globulin levels with mean values 150% of those seen in normal adults, whereas IgM was decreased to a mean of 62% of normal.[15] Elevated levels could not be correlated with a history of infections.

We conclude that HS is a localized chronic infection due not to a generalized defect in host defense but rather to local factors leading to obstruction of the apocrine glands. Once initiated, the process of inflammation perpetuates itself with further impairment of the glandular drainage. Early in the disease, broad spectrum antibiotics and elimination of the local factors might reverse the process, but in the chronic phase, surgery remains the only curative mode of therapy. Patients treated with radical surgery to remove all involved apocrine glands have no in-site recurrence and no apparent predisposition for infection elsewhere.[3]

This investigation was supported in part by grant AA 00332 from the National Institute for Alcohol Abuse and Alcoholism.

Topical Chemotherapy and Immunotherapy of Mycosis Fungoides

Intermediate-Term Results

Eric C. Vonderheid, MD; Eugene J. Van Scott, MD;
Waine C. Johnson, MD; David A. Grekin, MD; Sucha O. Asbell, MD

• A group of 220 patients with mycosis fungoides (MF) and other lymphomatous diseases was treated with sustained topical applications of dilute aqueous solutions of mechlorethamine hydrochloride for intervals ranging in excess of seven years. Response to treatment, immunologic responsiveness, and subsequent course and survival were inversely related to magnitude of disease at time of starting treatment. Relapses were common, and in most instances were related to failure of maintenance of topical therapy rather than to drug resistance. In selected patients topical therapy with an analog of mechlorethamine (nor-mechlorethamine) and with topical immunogenic agents provided additional improvement.
(*Arch Dermatol* 113:454-462, 1977)

Mycosis fungoides (MF), a progressive cutaneous malignant lymphoma that eventually involves lymph nodes and other internal organs, has remained a lethal disease in a substantial proportion of patients. In an earlier publication[1] we reported that whole body topical applications of dilute aqueous solutions of mechlorethamine hydrochloride were effective treatment of early MF, with 56% maintained in a disease free state at the end of therapy periods of up to four years.

We presented data on the abolition and prevention of delayed hypersensitivity to mechlorethamine, a frequent occurrence with topical mechlorethamine therapy. It was found that cutaneous delayed hypersensitivity to mechlorethamine could be abolished or diminished by giving daily intravenous infusions of small doses of mechlorethamine. We also reported that contact sensitization could be prevented by initial induction of specific immunologic tolerance to mechlorethamine by means of giving small weekly intravenous injections of mechlorethamine three to five weeks prior to initiating topical mechlorethamine therapy. In 12 patients so pretreated, no instance of a delayed hypersensitivity occurred, in comparison to a frequency of 38% in the control group of 56 patients.

A follow-up evaluation of our results with topical mechlorethamine therapy, now covering an additional three years, seems appropriate. We include additional data on immunologic reactivity in MF, the therapeutic effect of delayed hypersensitivity reactions imposed on extensive areas of the body, topical therapy with an mechlorethamine analog (nor-nitrogen mustard), and a reevaluation of the subject of induction of immunologic tolerance to mechlorethamine.

DIAGNOSTIC CLASSIFICATION AND STAGING

Clinical data of 192 patients with MF and 28 patients with various other lymphomatous dermatoses evaluated during the interval from Sept 1, 1968, to Sept 1, 1975, are presented in Table 1. Diagnostic criteria for each grouping were based on conventional clinical and pathologic features.[2-4] (The biopsy specimens were reviewed by one of us [W.C.J.] to assure consistent histopathologic interpretation.) The MF patients were further subclassified into three types according to the predominant clinical features of cutaneous disease when first observed by us: infiltrative plaque-tumors (classical Alibert MF); poikilodermatous lesions with or without infiltration; and diffuse erythroderma (including those otherwise identified as having the Sezary syndrome). The clinical staging system previously used (Table 2) has been followed with the slight modification in connection with patients having erythrodermic disease. Since lymphadenopathy (stage 4) was consistently present in these patients, the cases were subdivided according to percentages of easily detectable circulating atypical mononuclear cells.

TREATMENT

The use of topical and intralesional mechlorethamine, procedures to induce immunologic tolerance prior to its use, and desensitization of allergic patients have been described in detail in the earlier report.[1] Briefly, for topical therapy with mechlorethamine, 10 mg of mechlorethamine powder are dissolved in 1½ to 2 ounces of water; a teaspoon of glycerin or vegetable oil may be added for patients with xerotic skin. The patient is instructed to apply the freshly prepared solution daily over the *entire* cutaneous surface, but relatively sparingly in the intertriginous zones. The dose and frequency of applications are adjusted according to any encountered irritation and response to therapy. In the event of slow responding disease, drug applications may be increased to two or three times daily, governed only by degrees of irritation that may arise. Topical painting usually has been preceeded by a series of small intravenous injections of mechlorethamine for the

4	Any of above	+	0
5	Any of above	+	+

purpose of inducing immunologic tolerance. For this, 200 μg of mechlorethamine was given as single rapid intravenous injections once weekly for a total of five injections; topical therapy was started at the end of the third or fourth week of injections. Other tolerogenic procedures, however, were also explored in smaller numbers of patients.

Tumors were frequently injected with a drug mixture prepared as follows: 100 μg of mechlorethamine hydrochloride, 1 ml of 2% triamcinolone acetonide suspension (to counteract inflammation due to mechlorethamine) and 1 ml of 1% lidocaine (to relieve pain following injection). Lesions were infiltrated at multiple sites, with 0.05 to 0.1 ml at each site.

In a few patients allergic to mechlorethamine, nor-mechlorethamine, an analog previously demonstrated to have antimitotic properties[5] was applied in a manner similar to that used for mechlorethamine by diluting 5 ml of 5% nor-mechlorethamine in absolute alcohol with 45 ml of water.

Systemic chemotherapy was provided in addition to topical therapy for patients with initial or later evidence of systemic disease (ie, stages 4 or 5) and for patients with rapidly progressive, unresponsive, or otherwise problematic intracutaneous disease. Various drugs were used, including mechlorethamine as a single agent or in combination with vincristine sulfate, procarbazine, and/or prednisone (MOPP); cyclophosphamide; or methotrexate. The dosage schedule used for intravenous mechlorethamine was what we have termed "slow dose," a schedule in which 2 mg of mechlorethamine is given daily for a usual total dose of 0.4 mg/kg.[6]

Topical immunotherapy was explored on selected patients, in which either mechlorethamine or dinitrochlorobenzene was used as the antigenic agent. Mechlorethamine was utilized usually in cases where spontaneous sensitization to mechlorethamine had occurred during the course of topical therapy; dinitrochlorobenzene was used in other cases, in which the procedure for induction of delayed hypersensitivity to dinitrochlorobenzene was as customarily used.[7] At the time of immunotherapy the patient's degree of sensitivity was determined by means of titrated patch testing to the appropriate antigen. In patients undergoing mechlorethamine immunotherapy 10, 1, and 0.1 μg of freshly prepared mechlorethamine, in 0.1 ml aqueous solution, were applied to 15 sq cm (3 × 5 cm) areas of clinically normal skin, distributed evenly over the test area, allowed to dry, and left uncovered. In patients undergoing dinitrochlorobenzene immunotherapy a similar titration using 250, 25, and 2.5 μg of dinitrochlorobenzene dissolved in equal parts of acetone and water were applied to 15 sq cm sites. The threshold of reactivity and the desired degree of reaction was determined by observing the test sites over the next 48 hours and the reaction graded as follows: no reaction, 0; erythema only, +1; erythema and edema, +2; erythema and vesiculation, +3; bulla formation and/or denudation, +4. Further titrations to smaller quantities were done as needed in a few cases where exquisite sensitivity existed to either antigen. Immunotherapy consisted of one or more applications of the antigen to most of the body surface areas in amounts gauged to provoke a distinctly discernible delayed hypersensitivity reaction (+2). In some patients, applications to discernible diseased areas only, generally to provoke a +3 reaction, were done. The resulting dermatitis was symptomatically treated with bland topical creams or wet dressings with or without antihistaminic drugs to relieve pruritus for approximately one week after the reaction appeared.

RESPONSES TO TOPICAL MECHLORETHAMINE

Table 3 summarizes the current status of 166 MF patients followed for a minimum period of six months treated with topical mechlorethamine and, if necessary, with other modes of therapy. A prognostic correlation is found between the initial magnitude of disease, as connoted by the clinical stage, and the current status. About half of patients with typical infiltrative MF apparently limited to the skin (stages 1 to 3) are currently free of detectable disease.

A similar prognostic correlation is found in erythrodermic patients when the percentage of circulating Sezary cells is used as an index of severity of disease. Patients with high percentages of circulating Sezary cells in general responded less well to therapy

than patients with low numbers of cells.

Table 4 presents data on those patients maintained on a regimen of topical mechlorethamine only. Topical mechlorethamine was found to be effective as a sole therapeutic agent in most patients with early disease, whereas patients with more advanced disease required additional forms of therapy, ie, systemic chemotherapy.

Data on the remaining 21 patients with miscellaneous lymphomatous diseases, are summarized in Table 5. Although the numbers are small, the therapeutic improvements in most patients have been less than those achieved in MF.

MAINTENANCE THERAPY WITH TOPICAL MECHLORETHAMINE

The therapeutic objectives in our patients have been (1) to induce a complete clinical remission, and (2) thereafter maintain the remission for sustained intervals. Table 6 presents data on the course of patients who achieved a complete remission. Any detectable clinical sign of renewed activity of disease, ie, visible dermatitis, was considered to be an indication of relapse, even in the absence of specific histopathologic confirmation. Of the 114 MF patients in whom a complete remission was achieved, in only 41 (36%) was the remission completely sustained. In 14 patients complete remissions have lasted for more than three years.

Survival curves of patients with MF as determined by an actuarial method[8] are presented in Fig 1 and 2. The numbers at each point denote the number of patients alive at the beginning of each time interval. Patients dying of causes probably unrelated to MF are recorded as being alive during the year of their death.

The major clinical problems encountered with topical mechlorethamine therapy were irritation, allergic sensitization, and therapeutic unresponsiveness. Mild irritation was commonly observed in intertriginous zones

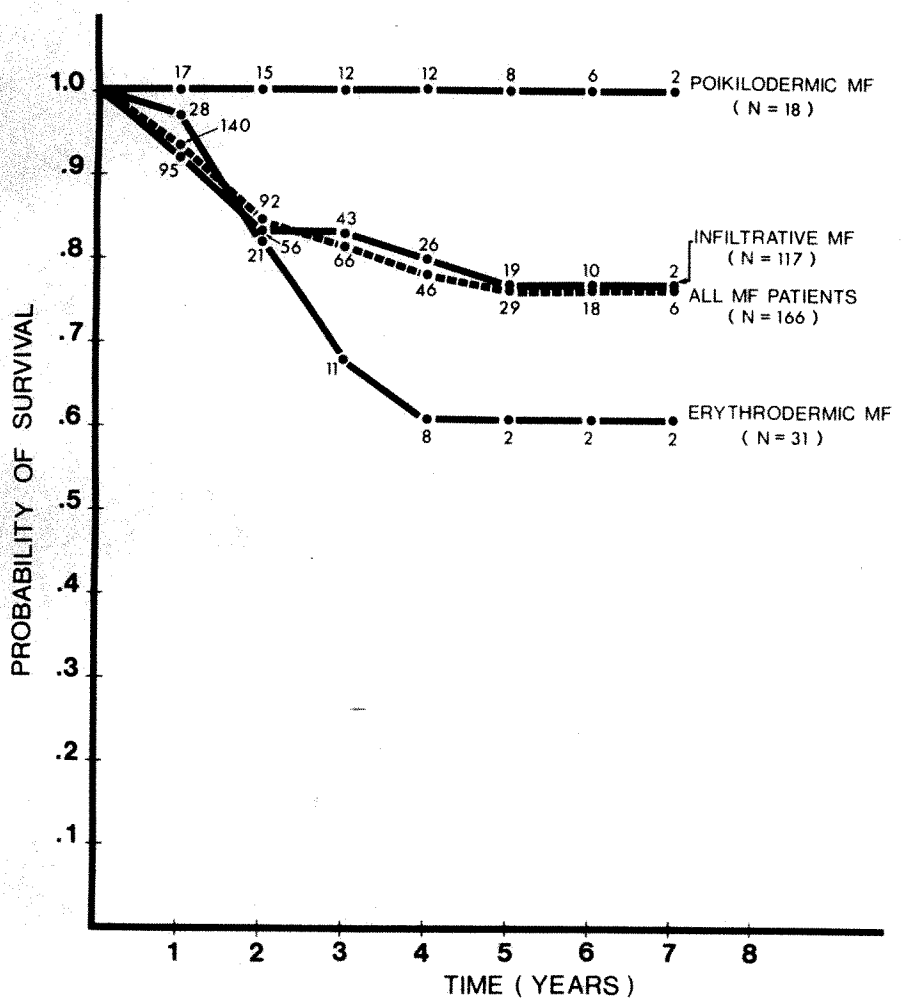

Fig 1.—Actuarial survival curves for MF patients according to clinical appearance.

and at lesion sites. Irritation required diminution of dose or frequency of applications in 11% of poikilodermic patients, 7% of patients with infiltrative lesions, and 23% of erythrodermic patients. Relative drug resistance, as judged by unusually slow or minimal resolution of lesions occurred in 6% of poikilodermic, 23% of infiltrative, and 29% of erythrodermic patients. Allergic sensitization of the delayed type, when occurring, usually was clinically apparent within 14 to 28 days after initial topical exposure to drug.

Recurrence of clinical disease following complete remission, occurring in many patients (Table 6), had variable causes. These included interruption of topical therapy because of irritation or allergic sensitization, patient noncompliance with prescribed procedures, acquired drug resistance, and new evidence of internal disease. Acquired unresponsiveness to therapy was fairly common in advanced stages of infiltrative MF and Sezary syndrome but also in 20% of patients with infiltrative MF, stages 1 and 2.

CORRELATION OF IMMUNOLOGIC RESPONSIVENESS WITH TYPE AND EXTENT OF DISEASE

Table 7 presents data on delayed hypersensitivity to dinitrochlorobenzene and mechlorethamine. Patients presenting with poikilodermic MF appear to have a normal immunologic responsiveness to dinitrochlorobenzene as compared to reported normal controls,[9,10] whereas those with other clinical forms seem to have a somewhat depressed responsiveness. These results augment those of an earlier report[11] that indicated a near normal responsiveness to dinitrochlorobenzene in patients with MF limited to the skin, a study that otherwise did not take into account stages of disease.

A comparison of dinitrochlorobenzene and mechlorethamine reactivity suggests that dinitrochlorobenzene is a more potent antigen than mechlorethamine. In support of this interpretation is the observation that few patients not sensitizable to dinitrochlorobenzene became sensitized to mechlorethamine, and that immunologic reactivity to mechlorethamine seemed relatively more suppressed with advanced disease. However, a definite conclusion on this cannot be established because the conditions for application of each are distinctly different; ie, dinitrochlorobenzene is applied in irritant quantities to a

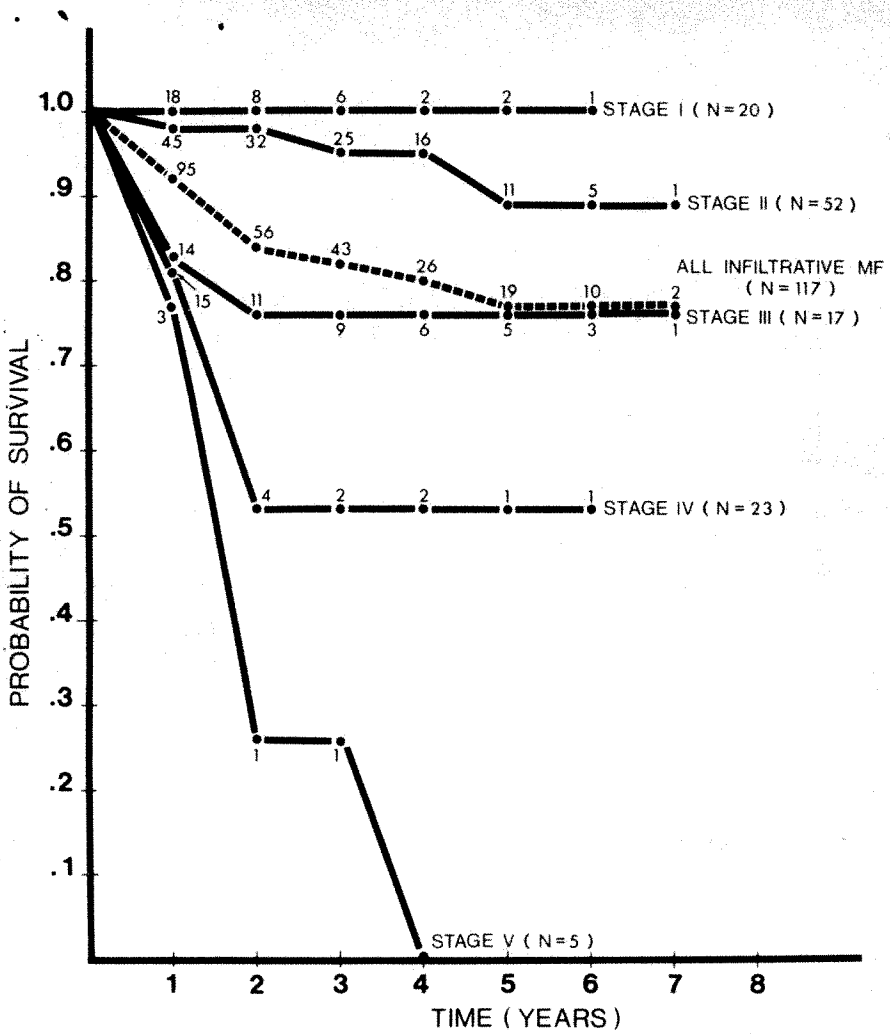

Fig 2.—Actuarial survival curves for infiltrative MF patients in different clinical stages.

small area of the skin, whereas mechlorethamine is applied in subirritant doses to the entire skin surface.

PROGNOSTIC SIGNIFICANCE OF INTACT IMMUNOREACTIVITY

In general, patients who were dinitrochlorobenzene-sensitive achieved clinical remission sooner (four months) than patients who were not sensitive (six months), although both groups eventually achieved remission in equal frequency. A slightly decreased frequency of MF-related deaths was observed at a given clinical stage in dinitrochlorobenzene-sensitive patients compared to the dinitrochlorobenzene-nonsensitive group (Table 8), but this difference may not be statistically significant. Furthermore, we have observed ten patients who eventually lost their ability to react to dinitrochlorobenzene, and this loss was associated with systemic dissemination of disease. These observations support the general factor in host defense to MF as with other forms of cancer.

INDUCTION OF SPECIFIC IMMUNOLOGIC TOLERANCE TO TOPICAL MECHLORETHAMINE

Initial observations presented in a previous report[1] suggested that the frequency of delayed hypersensitivity to mechlorethamine could be diminished by small preliminary injections of mechlorethamine intravenously. Since the present review of accumulated data indicates that immunologic responsiveness to mechlorethamine varies considerably with different clinical presentations and stages, reassessment of this subject seems necessary to assure exclusion of bias on the basis of patient selection.

Table 9 presents a summary of results with two tolerogenic schedules according to clinical classification. The patients presented in this table excluded all who had received any previous therapy. However, a selection bias may still exist within these groups, ie, schedule A contains proportionately more patients at stage 1 and fewer at stage 2 than the control group, a difference probably favoring greater inherent immunoreactivity within the schedule A group. Schedule B, which differs from schedule A only by the addition of oral mechlorethamine to the regimen, appears to have induced tolerance more successfully. The statistical significance of these differences however remains uncertain, and no further conclusions can be drawn by us at this time.

DESENSITIZATION TO MECHLORETHAMINE

As previously reported,[1] small doses of intravenous mechlorethamine administered daily may achieve states of desensitization to enable resumption of topical therapy. The procedure unfortunately requires one or more hospitalizations of one to four weeks' duration and has potential risks. Therefore other therapeutic options, eg, immunotherapy or nor-mechlorethamine, have been preferred by us recently.

We have observed 60 instances of delayed contact hypersensitivity to mechlorethamine, 16 of which were related to prior topical therapy initiated by other physicians. Thirty-one patients were hospitalized for the intravenous desensitization procedures. In seven cases, the procedure was discontinued abruptly because of the development of linear dermatitis overlying the vein of the infusion, a complication generally necessitating lower doses and extended hospitalization periods. In ten patients, desensitization was achieved with one hospitalization, permitting resumption of topical therapy without further difficulty. In 12 patients hyposensitization was achieved, as assessed by serial patch testing. Neither desensitization nor hyposensitization was reached in two patients. The likelihood of successful desensitization seemed better

with patients manifesting lesser degrees of reactivity to mechlorethamine on the onset. Complete desensitization of the hyposensitized group was eventually achieved in four cases after a second attempt and in three additional cases after several attempts. Thus 17 of 24 patients (71%) have been able to resume sustained applications of topical mechlorethamine following one or more desensitization courses of intravenous mechlorethamine.

INFLUENCE OF UNINTENTIONAL DELAYED HYPERSENSITIVITY REACTIONS TO MECHLORETHAMINE ON SUBSEQUENT COURSE OF DISEASE

Spontaneous development of an unintentional delayed hypersensitivity reaction during topical mechlorethamine therapy appears to have a beneficial effect on the short-term course of MF (Table 10). Of 39 patients with active MF at the time of the spontaneous delayed hypersensitivity reaction, which necessitated discontinuation of the drug, 15 (38%) were subsequently noted to lose all evidence of their disease, without additional therapy except for the brief administration of a topical or systemic corticosteroid preparation for the allergic reaction. At the time of the reaction most of these patients had improved partially from the influence of the preceding mechlorethamine therapy such that a lesser degree of disease involvement was present. Of interest, the median time to achieve a complete remission in these patients was about two months, and the duration of remission seemed to be inversely correlated to the clinical stage at the time of the delayed hypersensitivity reaction.

Patients with infiltrative MF seemed particularly likely to benefit from a delayed hypersensitivity reaction. One patient, however, converted from infiltrative MF to the Sezary syndrome following the delayed hypersensitivity reaction.

OBSERVATIONS ON INTENTIONALLY INDUCED DELAYED HYPERSENSITIVITY REACTIONS (IMMUNOTHERAPY)

Based on the foregoing and on previous observations that delayed hypersensitivity reactions have beneficial effects on individual lesions,[12] intentional topical immunotherapy using mechlorethamine or dinitrochlorobenzene as antigens was given to 19 patients with MF (Table 11). Complete clearing of clinically detectable disease followed immunotherapy in eight (42%) patients.

In the first few months following a single course of immunotherapy, a moderate decrease in the magnitude of lesion infiltration was observed in most patients. The benefits were more difficult to assess in poikilodermic MF, and in one patient with erythrodermic MF the disease transiently seemed to worsen. Thus, the majority of our patients required more than one course of immunotherapy to achieve complete remission.

The duration of remissions have ranged from 2 months to beyond 22 months without any further treatment. Application of dinitrochlorobenzene or mechlorethamine solutions either to the whole body or to lesions alone produced complete clinical remission. Although the numbers are small, the duration of remission seems to be somewhat longer following whole body applications.

The complications of immunotherapy were excessive pruritus and occasional secondary skin infections. Of interest, several patients became less sensitive to mechlorethamine after

repeated courses of topical mechlorethamine immunotherapy.

TOPICAL THERAPY WITH NOR-NITROGEN MUSTARD (PRELIMINARY OBSERVATIONS)

Nor-nitrogen mustard (nor-mechlorethamine) was utilized as topical treatment for 3 patients with poikilodermic MF, 34 patients with infiltrative MF, and in 7 patients with erythrodermic variants. The indications for its use included contact hypersensitivity to mechlorethamine (24 patients); as a primary drug when mechlorethamine was precluded by irritation or resistance (9 patients); and as a primary drug for an initial four-week interval, ie, a period selected for induction of tolerance to mechlorethamine (11 patients).

Delayed hypersensitivity reactions to nor-mechlorethamine developed in 11 patients. In ten patients already allergic to mechlorethamine, the reaction to nor-mechlorethamine developed on first exposure, indicating a 42% frequency of an immunologic cross reactivity between these compounds. One additional patient who never applied mechlorethamine developed delayed hypersensitivity to nor-mechlorethamine indicating the potential of primary sensitization to this drug.

Of 33 patients who received nor-mechlorethamine uncomplicated by delayed hypersensitivity, 17 patients improved to a measurable degree during its use, with complete eradication of lesions in 5 patients. The responsiveness to nor-mechlorethamine seemed somewhat less than with usual doses of topical mechlorethamine. It is concluded that nor-mechlorethamine can be effectively used in the topical treatment of early-stage MF, and that higher topical dosages for longer intervals may be required to improve treatment results.

FREQUENCY OF VARIOUS EPITHELIAL AND INTERNAL NEOPLASMS IN PATIENTS RECEIVING A TOPICAL NITROGEN MUSTARD

Since systemically administered mechlorethamine is carcinogenic in animals,[13] an important consideration is whether topical mechlorethamine, when applied over long periods of time, will increase the incidence of epithelial or other neoplasms. To investigate this possibility, the duration of topical mechlorethamine usage in our patients was compared to the observed numbers of epithelial and internal neoplasms. Patients having received prior therapy known to be carcinogenic, ie, arsenic or whole body radiation, or those giving a history of a prior epithelial neoplasms were excluded from the analysis.

Of 140 patients who received topical mechlorethamine for a three-year interval or less, 6 (4%) instances of an epithelial neoplastic growth (2 actinic keratoses, 2 squamous cell carcinomas, 1 Bowens disease, and 1 basal cell carcinoma) were confirmed by biopsy. Of 26 patients treated in excess of three years, 7 (27%) patients developed at least one type of epithelial neoplasm and, in 4 patients, the lesions were of several types. The single lesions included two instances of actinic keratoses and of Bowens disease; the lesions on the other four patients include both actinic keratoses and squamous cell carcinomas. All were noted to develop in the sun-exposed areas of white-skinned persons. There have been no examples of malignant melanoma. Thus, an increased frequency of actinic keratoses and squamous cell carcinomas may be emerging in our patients, perhaps by augmenting precarcinogenic solar damage. These conclusions are based on a small number of patients observed over a relatively short time interval, and may or may not be valid.

Six patients have developed internal neoplasms. The tumor types included carcinomas of the esophagus, pancreas, and colon; bronchoalveolar carcinoma; adenomatous carcinoma of the lung (two cases); and a pituitary tumor of unknown type. Four of these patients had received systemic alkylating agents or other potential carcinogens in the past. There appears to be little evidence at this time to implicate topical mechlorethamine as a cause of internal cancer.

COMMENT

Historically, both radiation and mechlorethamine have been recognized as effective therapeutic modalities for MF.[14] Recently, better utilization of each has produced sustained remissions to the point that "cure" is now considered possible. Important to both are early and adequate treatment, while the disease remains localized to the skin.

With radiation therapy, whole body treatment without serious internal side effects is now possible with high energy electrons. In 1971, Fuks and Bagshaw[15] reported that aggressive administration of whole body electron beam therapy could produce long remissions and probable cures of MF limited to the skin. Of 132 patients treated, 14 (11%) achieved sustained remission for intervals ranging from 3 to 14 years and may be considered cured on the basis of actuarial survival data.[16] No remissions beyond one year occurred when tumors were present in the skin. The treatment has the advantage of not requiring maintenance therapy but is limited to special centers and in some patients may cause cutaneous side effects such as

dermatitis and atrophy. A direct comparison with our results is not possible since the clinical classifications are somewhat different.

In 1973, Van Scott and Kalmanson[1] showed that complete remissions of MF could be achieved if dilute solutions of mechlorethamine were regularly applied to the entire cutaneous surface.[1] It is now apparent that recurrences of MF will often develop if the treatment is not adequately delivered. Fourteen patients have remained completely free of disease from three to seven years after remission, and further experience with topical mechlorethamine is needed to determine whether cure is actually achieved. The ideal maintenance regimen for the patient in complete remission, ie, dose, frequency, and duration of topical mechlorethamine therapy, has not been established at this time. In practice we currently continue whole body topical therapy once daily for six months after complete remission has been reached, and thereafter at lesser frequencies for a period of at least three years following complete remission.

Our exploratory experience to date with immunotherapy indicates this form of treatment might consistently induce clinical remissions. Histologic changes followed delayed hypersensitivity reactions imposed on lesions of MF have shown rises in lymphocyte proportions with decreases in atypical hyperchromatic "MF" cells.[17]

Our poor results in maintaining complete remissions in patients with tumors (ie, stage 3) suggest that extracutaneous involvement may go undetected in many instances. Indeed recent information from staging laparotomies indicates that the tumor stage is often associated with ultrastructurally detectable disease in the lymph nodes and other internal organs.[18] Furthermore, we have observed that the cellular composition of tumors at advanced stages provides substantial prognostic value; that is, tumors composed of a predominance of atypical histiocytoid cells generally respond poorly to mechlorethamine treatment while tumors with a predominance of lymphocytoid cells have a good response (unpublished observations).

In conclusion, treatment of MF today can be optimistic, with long remissions now possible from adequate whole-body therapy of early disease. Our experience using topical mechlorethamine for its chemotherapeutic properties, which are apparently separable from its immunogenic properties, indicates that recurrences may occur when maintenance applications are too infrequently applied. Therefore sustained intensive applications of mechlorethamine at a dose and frequency to maintain a disease-free state for a minimum period of three years are recommended. It seems probable that immunotherapy will further augment the benefits of either topical mechlorethamine or electron beam therapy.

This investigation was supported in part by grant 5 P01 CA11536 and 5 M01 RR 349 from the National Institutes of Health.

Dorothy Rose, Susan Corbett, and the staff of the Clinical Research Center, Temple University Hospital, gave assistance with our patients.

Vasculitis in Granuloma Annulare

Histopathology and Direct Immunofluorescence

Mark V. Dahl, MD; Susanne Ullman, MD; Robert W. Goltz, MD

• Biopsy specimens from patients with granuloma annulare were studied by conventional light and immunofluorescence microscopy. In six of 20 patients, IgM was present in blood vessels of involved skin, and C3 was present in blood vessels in ten of 20 patients. In addition, IgM, C3, or fibrinogen were observed at the dermal-epidermal junction of eight patients. Necrobiotic areas contained fibrinogen. A retrospective histopathologic study of 38 biopsy specimens from other patients with granuloma annulare showed blood vessels with vessel wall necrosis, fibrinoid change, thickening, or occlusion in most specimens. Nuclear dust and extravasation of RBCs were also noted. These findings suggest that an immunoglobulin-mediated vasculitis may be involved in the pathogenesis of granuloma annulare.

(*Arch Dermatol* 113:463-467, 1977)

Granuloma annulare is characterized by necrobiotic granulomas surrounded by a palisade of histiocytic cells.[1-4] The pathophysiologic events leading to formation of a necrobiotic granuloma are unknown. Biopsy specimens from lesions of granuloma annulare frequently show blood vessel thickening.[5] This suggests that occlusion or other events relating to blood vessels may be at least partially responsible for the necrobiosis. In order to examine this possibility, we studied vascular changes in biopsies from patients with granuloma annulare by light and immunofluorescence microscopy.[6]

PLAN OF STUDY

The study consists of two parts. Retrospectively, histopathologic sections from 38 patients with unequivocal granuloma were studied for the presence of pathologic alterations of blood vessels. Prospectively, frozen tissue sections from 20 other patients with granuloma annulare were studied for the presence of immunoglobulins, complement, and fibrinogen.

CLINICAL DATA

Biopsy specimens in which granuloma annulare had been considered in the histopathologic diagnosis were reviewed without prior identification. Only those specimens judged diagnostic of granuloma annulare by histopathologic criteria[1] were retained for further study. Of these, the prebiopsy clinical diagnosis was granuloma annulare in 38 patients, and the histopathologic part of this study was confined to biopsy specimens from these 38 patients.

Biopsies for direct immunofluorescence were performed on 20 other patients. All had a papular eruption compatible with granuloma annulare. The diagnosis was confirmed by biopsy specimens from all patients. Clinical data are summarized in Table 1.

METHODS

Histopathological Findings

Histopathologic sections stained with hematoxylin and eosin were examined for each of the following features: (1) swelling of endothelial cells; (2) thickening of blood vessel walls; (3) fibrinoid change of vessel walls, (4) necrosis of vessel walls; (5) occlusion of vessel lumina; (6) karyorrhexis (nuclear dust) in perivascular tissues; and (7) extravasation of RBCs. The presence of any of these features in any part of the biopsy specimens was recorded.

Immunofluorescence

Specimens were processed for direct immunofluorescence as previously described.[7] Briefly, 4-8 μ cryostat-cut sections were air dried for 15 minutes, washed in pH 7.2 phosphate-buffered saline for 15 minutes, and incubated 30 minutes with an appropriate dilution of antihuman IgG, IgA, IgM, C3, or fibrinogen labeled with fluorescein.

Blocking experiments with appropriate unconjugated antisera to IgG, IgA, IgM, C3, and fibrinogen were performed on adjacent cryostat-cut sections from each biopsy specimen. Prior to incubation with conjugate labeled with fluorescein, these sections were incubated three hours with unconjugated antisera and washed for 30 minutes with pH 7.2 phosphate-buffered saline. Occasionally, blocking incubations were continued for 12 hours.

Rabbit IgG, labeled with fluorescein-isothiocyanate, specific for human γ, μ, and α chains, complement C3, and fibrinogen was used (Dako, Copenhagen). The specificity of the antisera was controlled by crossed immunoelectrophoresis, and the

conjugated antisera against γ, μ, and α chains were tested on myeloma bone marrow cells. The antibody titer of all conjugates was 100. The titer denotes the number of micrograms of antigen that must be added to 1 ml of antibody to obtain a supernatant containing neither antigen nor antibody,[8] ie, if the titer is 100, 1 ml conjugate absorbs 100 mg pure antigen. The total protein concentration of the conjugates was 1.8 mg/ml. The fluorescein:protein ratios of all conjugates was 0.63 ± 0.03, estimated as the extinction ratio E 495 nm/E 278 nm. This corresponds to a molar F:P ratio of 2.3.[9] The working dilutions of the conjugates were as follows: anti-IgG 1:20, anti-IgM 1:10, anti-IgA 1:10,

Fig 1.—Left, Vasculitis in granuloma annulare. Three affected vessels are seen in midfield (arrow). They adjoin a typical necrobiotic focus of granuloma annulare, seen at the middle right (hematoxylin-eosin, original magnification ×100). Right, Higher magnification of left. Fibrinoid deposits and necrotizing changes in these vessels indicate the presence of significant vasculitic disease (hematoxylin-eosin, original magnification ×250).

Nuclear dust	13/38
Extravasation of RBCs	10/38

anti-C3 1:10, and anti-fibrinogen 1:20.

Analogous unlabeled rabbit antisera were used for blocking experiments. The antibody titers of these antisera were as follows: anti-IgG 600, anti-IgM 400, anti-IgA 400, anti-C3 400, anti-fibrinogen 300. The total protein concentration of each antisera was 7 to 8 mg/ml. Blocking experiments were performed with undiluted antisera.

Sections were examined for the presence of fluorescence with a Leitz fluorescence microscope equipped for transmitted light illumination, using an Osram HBO 200 lamp, an interference filter with a red contrast band (Optic Laboratory, Copenhagen), a dark-field condensor, and a 2-mm OG 515 nm matched glass barrier filter.

Adjacent frozen tissue sections were stained with hematoxylin and eosin and examined by light microscopy. This step was undertaken to confirm that a necrobiotic granuloma was present in the biopsy specimen processed for direct immunofluorescence.

Biopsies of clinically uninvolved skin from the upper outer arm or buttock were obtained from seven patients (patients 4, 9, 10, 13, 14, 18, and 20) and processed for direct immunofluorescence and light microscopy in an analogous fashion.

Serum Studies

Values for antinuclear antibody, rheumatoid factor, total hemolytic complement (CH50), and fasting blood sugars were determined in seven patients whose biopsies contained IgM or C3. Hepatitis associated antigen and cryoglobulins were also determined in two of these patients.

RESULTS

Histopathology

Results are summarized in Table 2. Vascular changes were observed in 35 of 38 sections. Swelling of vascular endothelial cells, thickening of blood vessel walls, occlusion of vascular lumina, fibrinoid change, and necrosis of blood vessel walls were observed in 33, 33, 32, 29, and 32 biopsy sections, respectively (Fig 1). Fibrinoid change and necrosis were particularly notable in or near areas of necrobiosis, but it

Table 3.—Summary of Immunofluorescence in Involved Skin of Granuloma Annulare in 20 Patients

Location	C3	IgG	IgM	IgA	Absent
Blood vessels	10	0	6	0	9
Dermal-epidermal junction	4	0	5	0	12

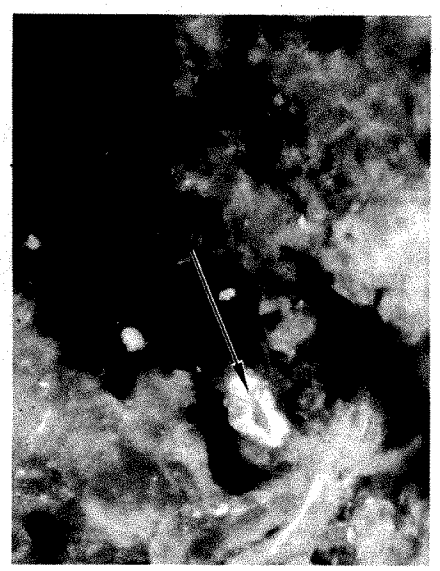

Fig 4.—Blood vessel of granuloma annulare (arrow) (patient 10) demonstrating deposition of C3 (antihuman C3, original magnification ×192).

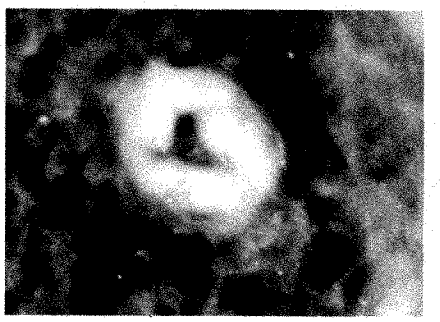

Fig 5.—The C3 in blood vessel of involved skin from patient 3 (antihuman C3, original magnification ×192).

was often difficult to be certain that the necrobiotic material in these areas was of vascular origin, since it sometimes merged imperceptably with the necrobiotic collagen of the granuloma itself.

Occlusion of one or more blood vessels was noted in 32 specimens, but most blood vessels were not occluded (Fig 2). In some specimens, occlusion and necrosis of a blood vessel was so advanced that the blood vessel itself was no longer defineable, but its presence was indicated by a collection of inflammatory cells similar to those surrounding necrobiotic vessels elsewhere.

A large collection of inflammatory cells usually surrounded blood vessels undergoing necrosis, and there was frequently extravasation of RBCs and production of nuclear dust. Inflammatory cells were predominantly lymphocytes or histiocytes although neutrophils were occasionally noted. Smaller numbers of inflammatory cells surrounded less severely involved vessels. Extravasation of RBCs was noted in 10 biopsy specimens; nuclear dust in 13.

Immunofluorescence

Results are summarized in Tables 1, 3, and 4. Deposits of fibrinogen were seen in the necrobiotic areas (Fig 3). This pathological finding was present in 13 of 18 biopsy specimens and correlated well with the presence of necrobiosis noted by light microscopic examination of adjacent hematoxylin and eosin stained sections (Table 2). Deposits of fibrinogen were so massive that blocking procedures had to be maintained for 12 hours before staining became negative or unquestionably weaker.

Complement C3 was demonstrated in blood vessel walls in 10 of 20 biopsy specimens of involved skin (Fig 4 and 5). Immunoglobulin M was present in six specimens. Fibrinogen was present in blood vessels of four of 18 biopsy specimens, but the intense fibrinogen staining of the necrobiotic granuloma itself may have masked fibrinogen in other vessels.

Deposits of IgM were noted at the dermal-epidermal junction of five biopsies (Fig 6). These deposits were granular and appeared similar to deposits commonly seen in biopsy specimens from patients with lupus erythematosus. All biopsy specimens

Table 4.—Summary of Fibrinogen in Involved Skin of Granuloma Annulare in 18 Patients

Location	Fibrinogen	Absent
Blood vessels	4	14
Dermal-epidermal junction	1	17

with deposits of IgM at the dermal-epidermal junction also had deposits of IgM in dermal blood vessels. Fibrinogen and C3 were also occasionally observed at the dermal-epidermal junction.

Immunoglobulin G and IgA were not detected in any biopsy specimen.

In all specimens, appropriate blocking experiments abolished or greatly reduced specific staining when compared to unblocked sections.

Serum Studies

Values for fasting blood sugar, total hemolytic complement, antinuclear antibody, and rheumatoid factor were normal or absent in all seven patients tested. Hepatitis-associated antigen and cryoglobulins were absent from sera of two patients.

COMMENT

These studies confirm our earlier

observations of immunoglobulins and complement in involved skin of granuloma annulare.[6]

The similarity of histopathologic vessel changes in lesions of granuloma annulare and in the Arthus reaction of experimental animals suggests that an immune-mediated, type 3 reaction might induce the vascular damage and subsequent necrobiosis.[10-15] In support of this hypothesis, IgM, complement, and fibrinogen are present in blood vessels in areas of granuloma annulare. Furthermore, granulomas can be produced in animals by subcutaneous injection of immune complexes formed in antigen-antibody equivalence, or antibody excess.[16]

There are, however, some differences between granuloma annulare and a typical type III immune vasculitis such as anaphylactoid purpura or the Arthus reaction. Lesions of granuloma annulare remain for weeks, months, or years, while lesions of allergic vasculitis disappear within days. In granuloma annulare, the infiltrate around blood vessels is composed predominantly of mononuclear cells rather than neutrophils, again suggesting a less acute process. Similarly, deposition of immunoglobulins and complement in blood vessels can be demonstrated even when lesions have persisted for months or years, whereas immunoglobulins can be demonstrated in blood vessels only during the first 24 hours after induction of the Arthus reaction.[11] These differences suggest that the immune reaction that may induce lesions of granuloma annulare is a chronic, ongoing one, perhaps produced by an immune reaction involving antibody and local tissue antigen.

Fibrinogen is present throughout the entire area of necrobiosis suggesting that this protein composes at least a portion of the necrobiotic material within the granuloma. It provides ready identification of the necrobiotic areas by immunofluorescence microscopy. In some patients, it is easier to recognize fibrinogen in necrobiosis stained with antihuman fibrinogen labeled with fluorescein, than it is to recognize necrotic material stained with hematoxylin and eosin.

Immunoglobulin M and C3 were present at the dermal-epidermal junction of some patients. Here these appeared similar to bands of immunoglobulins and C3 observed in skin of patients with lupus erythematosus,[17] porphyria,[18] leprosy,[19] graft versus host reaction,[20] dermatitis herpetiformis,[21] facial granuloma,[22] and occasionally other dermatoses. Similar deposits are also observed in allergic vasculitis such as anaphylactoid purpura,[23,24] and urticarial vasculitis.[25] Their significance is unknown but may be important. These deposits may represent collections of immune complexes formed in vessels, dermis, or other tissues that have lodged against the epidermal basement membrane. The analogous deposits seen at the dermal-epidermal junction of patients with lupus erythematosus lie just on the dermal side of the epidermal basal lamina.[26]

The cause of granuloma annulare is still unknown. It is possible that histologic changes and immunofluorescence of vessels are only secondary phenomena. However, the presence of immunoglobulins and complement in blood vessels of many patients with granuloma annulare suggests that a chronic immune vasculitis may be involved in the pathogenesis.

This investigation was supported by Public Health Service grant 5T01 AM 05560, and a grant from the Diabetes Research Fund of the American Diabetes Association–Minnesota Affiliate.

Isadore Fisher, MD, referred the initial patient, and Charles Balogh, MD, and Sheldon Mandel, MD, referred numerous other patients for study.

Thrombocythemia as a Cause of Erythermalgia

Keith G. Redding, MD

• **Erythermalgia is a distinctive clinical entity characterized by local redness, warmth, and burning pain in the distal portions of the extremities. In this study, erythermalgia was observed in two patients with myeloproliferative disease. A new theory suggesting abnormally rapid platelet aggregation as a cause of erythermalgia was advanced. The following evidence is presented: (1) histologic evidence of thrombi occluding the arterioles and probably composed of platelet aggregates; (2) reversal of the clinical findings with platelet aggregating drugs, such as heparin sodium and acetylsalicylic acid; (3) disappearance of the erythermalgia with the adequate control of the myeloproliferative disease.**

(*Arch Dermatol* 113:468-471, 1977)

Erythermalgia has variously been called erythromelalgia and erythralgia since its original description by Weir Mitchell in 1878.[1] I prefer the first term because it emphasizes all three of the essential components of the syndrome: local redness, warmth, and burning pain of the extremities. These features are initiated by the internal heat of exercise or by external heat, and are diminished by cold.

Of 51 cases reviewed by Babb et al,[2] 30 were considered to be idiopathic because there was no associated disease. The idiopathic form appeared to occur in a younger population, more often male, and it was usually self-limited. The other 21 cases were associated with diabetes, venous insufficiency, hypertension, rheumatoid arthritis, or lupus erythematosus; particularly striking were ten cases of myeloproliferative disease, in some of which erythermalgia preceded all other manifestations by several years. Also described in the literature[3] is a familial group of 19 patients whose syndrome seemed to be inherited along with glomerulonephritis in a sex-linked dominant fashion.

Erythermalgia should be easily distinguished from other causes of painful limbs. The characteristic history of aggravating and relieving factors and careful delineation of the pain to the warm, reddened areas of the involved limb are almost pathognomonic. A history of cold exposure distinguishes the nodules of chillblains or cold panniculitis; a normal or cool temperature is found in arteriosclerosis obliterans, thromboangiitis, or peripheral neuropathy; weight bearing is the chief initiator of pain in osteoarthritis, metatarsalgia, march fracture, plantar neuroma, or plantar fasciitis.

The pathophysiologic nature of erythermalgia has, over the years, remained quite unknown. I recently have had the opportunity to study two patients with the syndrome, both in association with myeloproliferative disorders. The results have suggested an important role of the platelet elements of the blood in their erythermalgia.

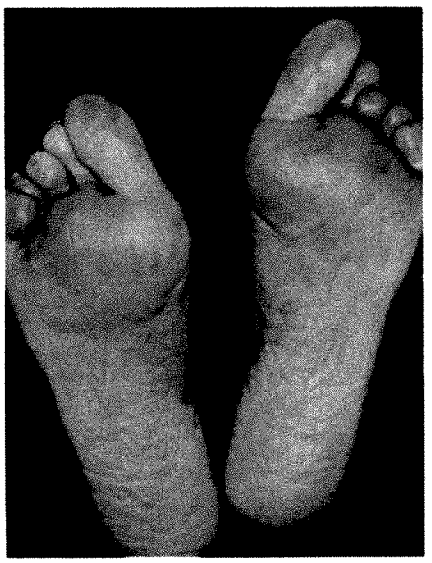
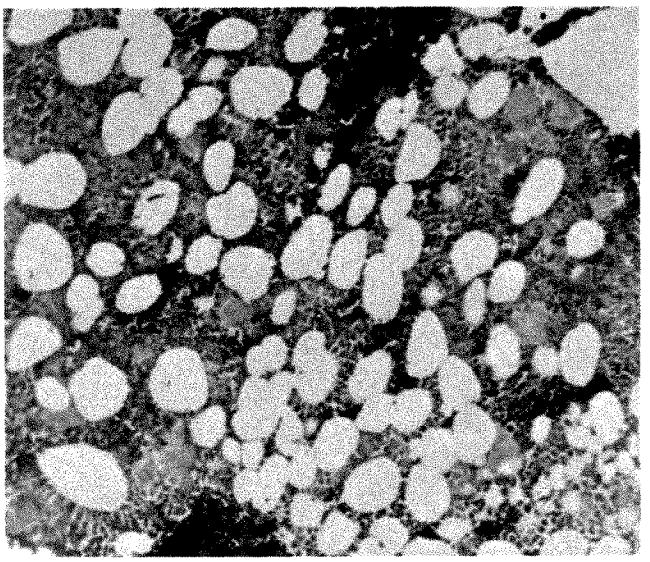
REPORT OF CASES

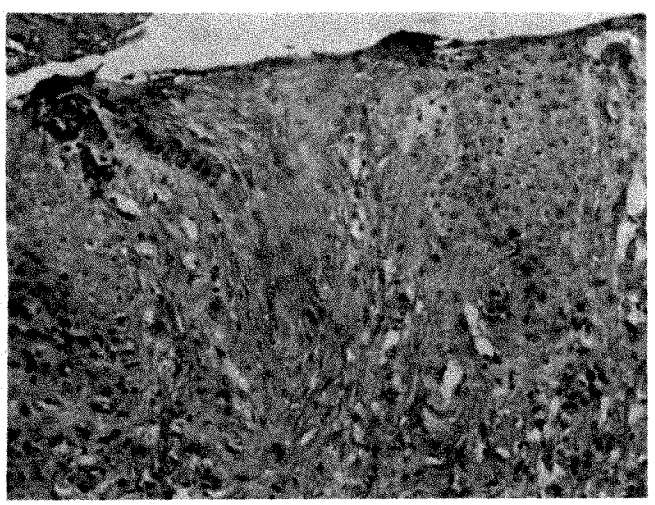
CASE 1.—A 72-year-old woman was first seen on Jan 7, 1974 because of continuous burning pain localized to patchy erythematous areas on the distal aspects of the feet and toes (Fig 1). The right little toe was cyanotic, but blanchable on diascopy. The erythematous areas were warmer than the surrounding skin and were very tender, though blanching, continuous pressure relieved the tenderness. Some immediate relief was gained by cooling the areas. Other than a few superficial varicosities and some onychomycosis, the local nutritional status and neurosensory status of the feet were good. The patient's general physical status was only fair because of long-standing asthma and compensated congestive heart failure.

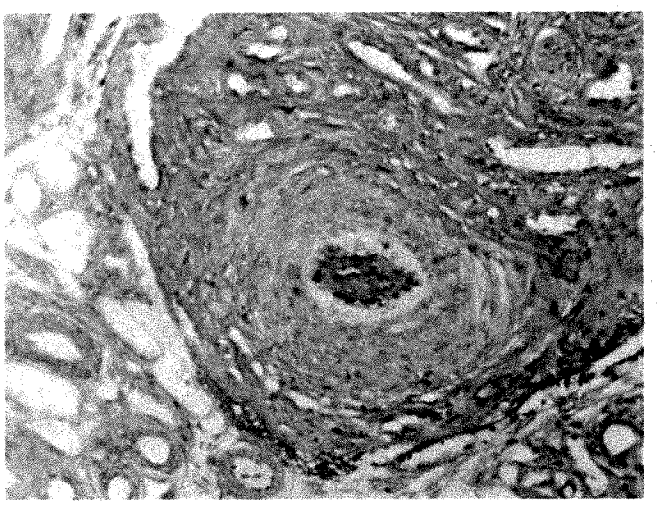
Laboratory evaluation revealed an initial hemoglobin level of 13.5 gm/100 ml, but a WBC count of 13,100/cu mm and a platelet count of 1,700,000/cu mm. The peripheral blood smear confirmed a marked thrombocythosis and showed a differential cell count of 74% neutrophils, 2% basophils, 4% eosinophils, 14% lymphocytes, and 5% monocytes. Examination of bone marrow from the iliac crest showed a marked increase in megakaryocytes with platelet budding (Fig 2). The leukocyte alkaline phosphatase score was abnormally high (123; control, 202; normal range, 14,100).

Results of punch biopsy of the cyanotic toe included "artifactual loss of the upper layers of epidermis." Also, thrombi oc-









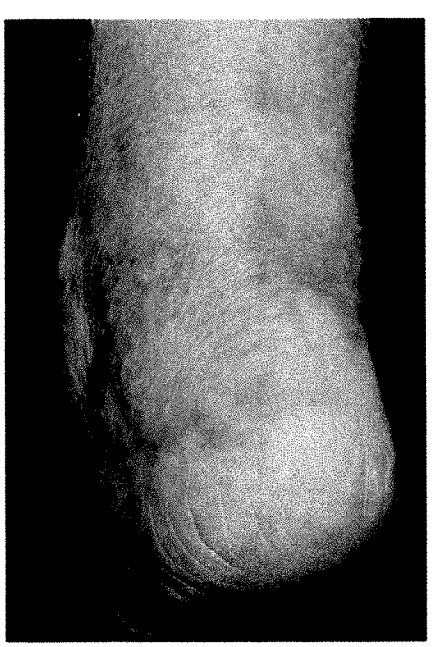


Fig 1.—Top left, Clinical picture of painful erythematous patches and cyanotic right little toe (case 1).

Fig 2.—Top right, Bone marrow specimen revealing hyperplasia of large pale eosinophilic megakaryocytes with platelet budding (arrow) (hematoxylin-eosin, original magnification ×400).

Fig 3.—Center left, Punch biopsy specimen from cyanotic toe. Upper layers of epidermis lost artifactually. Papillary dermis edematous with bright eosinophilic thrombi in some capillaries (hematoxylin-eosin, original magnification ×400).

Fig 4.—Center right, Lower part of dermis of same slide as Fig 3. Arteriole completely occluded by thrombus (hematoxylin-eosin, original magnification ×400).

Fig 5.—Bottom left, Warm painful erythema over heel (case 2).

cluded many capillaries in the edematous dermal papillae. Dermal vessels were dilated, and thrombi totally occluded some arteries, arterioles, and venules (Fig 3 and 4). The thrombi were fibrin-negative on staining with phosphotungstic acid hematoxylin and were granule-negative on staining with PAS.

Normal laboratory findings in this patient included serum electrolyte determinations, coagulation studies (Ivy bleeding time, prothrombin time (PT), partial thromboplastin time (PTT), and fibrin split products), porphyrin screening, rheumatoid arthritis titer, lupus erythematosus fluorescent antibody titer, VDRL test for syphilis, and serial 24-hour urine excretion studies for 5-hydroxyindoleacetic acid (5-HIAA).

The patient's hematologic diagnosis was essential thrombocythemia, which is a myeloproliferative disorder. Because of the biopsy evidence of continuing thrombosis, the patient was treated with heparin sodium by intravenous infusion sufficient to maintain PTT between 1.5 to 2.5 times control. Within minutes the patients erythermalgia was markedly relieved, and she was able to ambulate. An intravenous dose of 3 μCi of sodium phosphate P 32 was given to retard the uncontrolled platelet production. Two weeks later, 9 mg of uracil mustard was given to further decrease the platelet count. Two weeks later the platelet count was within normal limits. During the total treatment period, heparin had to be continued without break to control the erythermalgia and thrombosis. When the platelet counts had reached normal levels, heparin was no longer required for control. The patient was discharged free of pain.

Ten weeks after the onset of her hematologic illness the patient died of complications of asthma. Postmortem findings also noted an enlarged spleen (470 gm; normal, 150 gm) with small follicles but with a congested and firm parenchyma. There was megakaryocytic hyperplasia of the bone marrow, which was consistent with her myeloproliferative disorder. Vascular thrombi in various stages of organization were noted both in the myocardium and in the kidneys. The cyanotic toe had mirrored the thrombotic episodes internally.

CASE 2.—A 68-year-old woman was first seen May 1, 1974 with typical history and findings consistent with erythermalgia of both feet (Fig 5). She had been known to have polycythemia rubra vera since 1967, but had never received adequate treatment. A painful purple spot had developed on her left leg in November 1973. The patient suffered a splenic infarct at that time. These lesions healed, but the feet had been painful since.

Her general health was only fair because of hypertension and idiopathic Parkinson disease. The local nutritional status and neurosensory status of her feet were judged to be normal.

Laboratory findings included a hemoglobin level of 18.1 gm/100 ml, a RBC count of 8,200,000/cu mm, a WBC count of 12,500/cu mm, and a platelet count of 710,000/cu mm. Differential cell count was 80% segmented neutrophils, 10% band forms, and 10% lymphocytes. The blood glucose value two hours after eating was 142 mg/100 ml, the BUN value was 21 mg/100 ml, and the serum uric acid value was 7.9 mg/100 ml.

Results of the following tests were within normal limits: chemistry studies for alkaline phosphatase, total serum bilirubin, total serum protein, serum albumin, lactic dehydrogenase, serum calcium, inorganic serum phosphate, serum cholesterol, and SGOT; chest x-ray film, urinalysis, coagulation studies (PT, Lee-White clotting time, Ivy bleeding time, and PTT), serum vitamin B_{12}, cryoglobulins, cryofibrinogens, cold hemolysins, brain scan, and VDRL test for syphilis. Serial 24-hour urine test results for 5-HIAA remained normal throughout the hospital stay. Serum serotonin concentration in blood drawn simultaneously from the femoral artery and vein were normal and equal.

This patient's feet had no cyanotic areas. A punch biopsy specimen from an erythematous area showed no discernible changes in the epidermis, some dilation of capillaries in the dermis, and no discernible thrombi in the vessels.

The patient's hematologic diagnosis was polycythemia rubra vera, which is another of the myeloproliferative disorders. The patient was given 8 mg of busulfan daily for the 31 days of her hospitalization. The hematologic counts gradually decreased until therapy was discontinued, at which time the hemoglobin value was 17.4 gm/100 ml, the WBC count was 4,700/cu mm, and the platelet count was 344,000/cu mm.

Several observations of the effects of different medications for her erythermalgia were noted. Plain propoxyphene in the maximum recommended dosages seemed to have no effect. Within 30 minutes of ingestion, acetylsalicylic acid (650 mg orally) produced subjective and objective improvement that lasted about four days. Heparinization by continuous intravenous infusion in the previously mentioned control range provided rapid relief for a four-day test period of administration. The erythermalgia subsided toward the end of the patient's hospital stay, so that she was discharged with her feet symptom-free.

COMMENT

To my knowledge, patient 1 is the first reported case of erythermalgia as the initial manifestation of essential thrombocythemia. Erythermalgia has been reported to occur in perhaps 3% of cases of polycythemia rubra vera.[2] The classification of either of these diseases within the broader group of myeloproliferative disorders is made on the basis of the predominant hyperplastic elements of the bone marrow. The former is predominantly hyperplasia of the megakaryocytic-platelet series; the latter is predominantly hyperplasia of the RBC series. Polycythemia rubra vera commonly has some increased numbers of the other series as well.

Both myeloproliferative disorders must be distinguished from reactive hyperplasias. Thrombocythemia can occur briefly following splenectomy and can occur in infection, hemorrhage, or disseminated malignant neoplasm.[4] Reactive polycythemia can occur in chronic lung disease, in mountain-dwellers, in cardiac right-to-left shunt, and in hematopoietin-producing tumors.

Some interesting features of erythermalgia must be taken into account in explaining its cause. Each of 31 patients had his own consistent "critical skin temperature point" measured in Babb's laboratory.[2] Above this temperature, whether produced by active exercise or passive external heating, the redness and pain appeared, and below it they disappeared. Range for the 31 patients was 31 to 36 C. Most of the patients achieved prolonged relief from single small doses of acetylsalicylic acid. Also, there is a strong association with myeloproliferative diseases.[5]

Jelinek,[6] Pepper,[7] and Catchpole,[8] have been proponents of a chemically mediated theory. They suggest a temperature-triggered release of pain-mediating and vasoactive substances in the sensitive areas of predisposed persons. These may be identical with the agents released in normal subjects by noxious stimuli, such as burns, frostbite, and ischemia. The known pain-producing substances in human plasma include acetylcholine, histamine, serotonin, prostaglan-

dins, and kinins.[9] All three authors implicate serotonin because their subjects with idiopathic erythermalgia responded to treatment with methysergide, an antiserotonin agent. We found no evidence in our patients of increased circulating serotonin or increased total excretion of serotonin metabolites. Our methods may, of course, be too crude.

Whatever chemicals may be involved, it is tempting to speculate that in our patients, the abnormal quantity of circulating platelets played a role in the erythermalgia. The platelets in the sluggish distal parts of the circulation were aggregating and releasing powerful vasoactive substances. When only small numbers of aggregates occurred, only erythermalgia was produced. When larger numbers were produced, cyanosis and microinfarction occurred. Even whole organs can become infarcted, such as the spleen in the second case. The success of heparin in relieving the conditions of both patients on several occasions fits with its known antithrombin action, slowing platelet aggregation and vasoactive chemical release. When the platelet counts became normal following appropriate therapy for the myeloproliferative disease, the erythermalgia disappeared. The second patient's prolonged relief from the single ingestion of aspirin is explained by knowledge of platelet physiologic characteristics. Aspirin permanently alters platelet membranes so that they cannot aggregate. Three or four days must elapse before sufficient numbers of new active platelets are generated. Then aggregation may begin again. This aggregation of platelets is dependent on a series of chemical reactions that are logarithmically temperature-dependent. When the temperature decreases below the "critical skin temperature point," erythermalgia is relieved.

Quantitative changes in the platelets in both of these patients appeared to play a major role in the production of their erythermalgia and to be a rational target for its therapy.

Hidrotic Ectodermal Dysplasia With Diffuse Eccrine Poromatosis

Ralph D. Wilkinson, MD, FRCP(C); Paula Schopflocher, MD, FRCP(C); Maria Rozenfeld, MD, FRCP(C)

• **Eccrine poromatosis (EP) of remarkable severity has been observed in a patient with hidrotic ectodermal dysplasia (HED), a member of the kindred originally described by Clouston. Neither the EP nor its association with HED has been previously reported.**

(*Arch Dermatol* 113:472-476, 1977)

We have observed hyperplastic alterations of the sweat ducts typical of eccrine poromata, but occurring in diffuse sheets over the distal parts of the extremities in a fashion previously unreported. The patient also manifested the severe form of hidrotic ectodermal dysplasia (HED), and is one of the kindred from southern Quebec described by Clouston.[1] Features of the poromata in this case suggest that the eccrine sweat gland may become the dominant element of the ectoderm on the distal extremities, and when this occurs may be a feature of the full expression of the Clouston HED.

According to Clouston's[1,2] description, the trait is dominant, and easily recognized by changes in the nails, hair, and skin. The nails reflect the severity of the genodermatosis. The nail plate is slightly thickened, discolored, and striated in the mildest, and obliterated by scar in the severest cases.

Recurrent infection of the nail is common and squamous cell carcinoma of the nail plate and palmar tissues was reported by Campbell and Keokarn[3] and Mauro et al.[4] Hair defects usually parallel those of the nail. In the mildest, the scalp hair may appear normal, but the outer one third of the eyebrows is sparse and the lashes and body hair may be sparse and short. In more severe cases the scalp hair is fair, short, and slow-growing. Genital hair may be absent. In the severest, there is total absence of scalp hair, usually noted from birth. Of the remaining follicular elements, the sebaceous glands are normal or atrophic and the apocrine glands and breasts usually well developed.

The skin surface appears normal, except for pebbling at the nail folds, erythema of the palms and soles, and coarse ridges and furrows about the joints. Pigmentation is often prominent on the knees, elbows, axillae, and phalangeal joints.

Ocular abnormalities were frequent.[5] The common abnormalities were strabismus, pterygium, conjunctivitis, and cataracts. Teeth were not typically affected. Other anomalies such as sensorineural hearing loss, polydactylism, and syndactylism have been reported.[6]

Eccrine sweat glands have been mentioned as unremarkable though functionally active in response to both emotional and thermal stimuli. Periungual pebbling of the skin surface has been prominent in some descriptions,[1] but no reference to these being papules related to eccrine duct tumors has been made. In the case reported below, the eccrine duct tumors, or poromata, comprise a prominent feature of clinical and histological presentation.

REPORT OF A CASE

A 44-year-old mother of nine children, a member of the family originally described by Clouston,[1] in Huntingdon, Quebec, had verrucous growths on the feet that bled and interfered with walking.

The history revealed that she was born with short brown scalp hair that was lost early in infancy. Eyebrows and lashes were absent from birth, and the body and extremities were always hair-free. In infancy, the fingernails were thick, convex, and brittle. Although the fingernails were lost at age 7, the toenails persisted as thick yellow masses that required frequent trimming. Perspiration was always copious during hot weather. Heat tolerance seems to have been reduced in recent years.

At age 40 years, small reddish spots appeared on the insteps. The lesions enlarged and appeared on the ankles and wrists, thence on the forearms and legs.

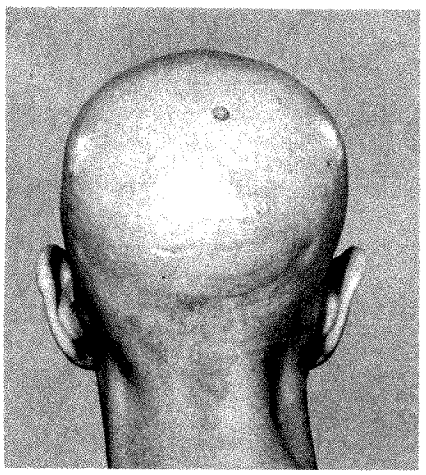

Fig 1.—Alopecia totalis universalis. Occipital papule was an intradermal nevus pigmentosus.

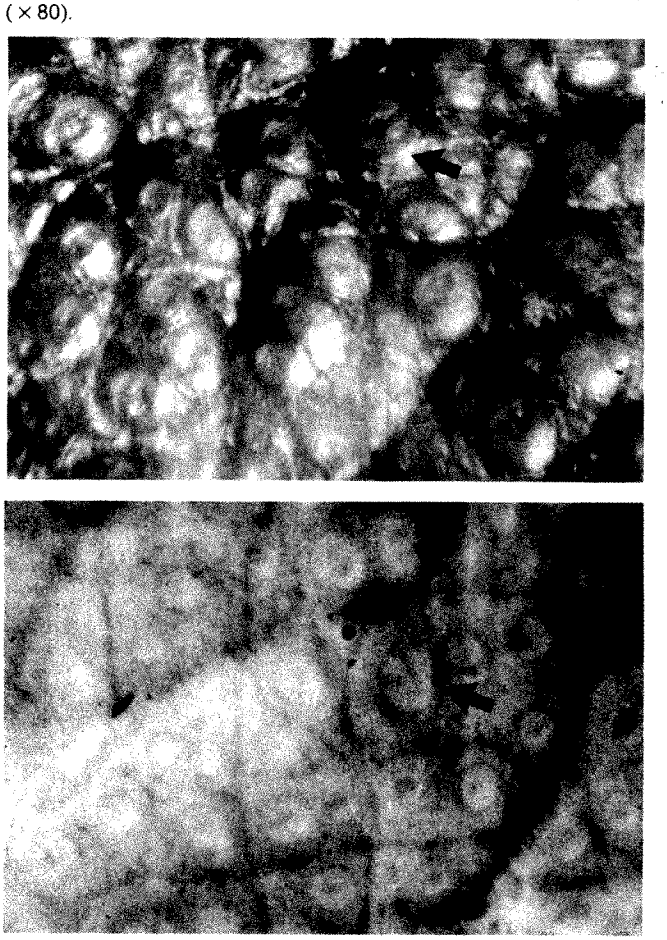
Fig 2.—Globose papules, solitary and clustered together, were present on the feet. Fingers were similarly affected.

Fig 3.—Globose papules were very prominent on lateral aspects of feet, ankles, and wrists. Note also plantar dyskeratosis and fissures.

Fig 4.—Small solitary papules and comedonic-like lesions were present on thighs, legs, and to a lesser extent, on trunk and upper extremities.

Fig 5.—Flexor surface of forearm. Poromatous nodules dominate surface features (top). Viewed through an oil film (bottom), capillaries can be seen in centers and rims of each nodule (arrow) (× 80).



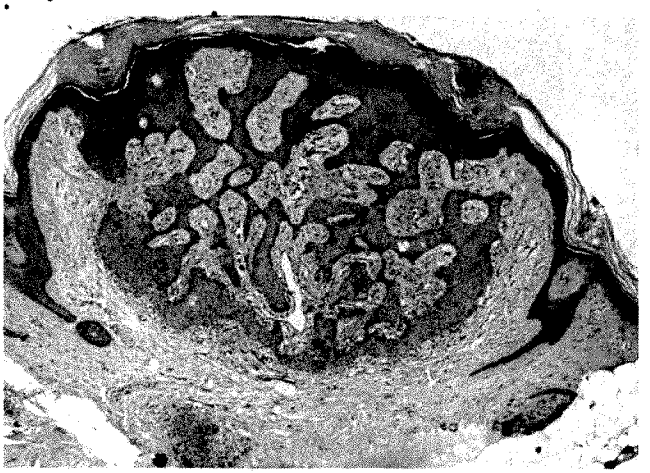


Fig 6.—Histopathology of a large globose papule from foot. There is hyperkeratosis with focal invaginations of keratin into epidermis. Thick, anastomosing tracts of small cuboidal cells proliferate into dermis. Tumor is embedded in highly vascular stroma (hematoxylin-eosin, ×50).

Fig 7.—Sweat duct in continuity with tumour and coursing through it. Hyperplasia of duct cells is noted in sweat duct adjacent to poroma (hematoxylin-eosin, ×200).

The palms were "cracked and sore."

In her family, members of many generations had poor nails and hair. The patient could not recall others with the tumors on the feet and wrists. In this respect she considered herself slightly different, although she described her sister as having small tumors too. The sister was not available for examination.

On system review, vision was poor in the left eye, and arthritic pains occurred in spring and during changes in weather, but no joint swelling was noted. The remainder of the review was noncontributory.

The patient appeared healthy, wore glasses and a hairpiece to effectively mask the features of the genodermatosis. Vital signs were normal, and the physical findings of importance were limited to the skin and eyes.

Hair was "totally" absent from the head, trunk, and extremities (Fig 1). Three hairs of 1 to 3 inches in length were present on the scalp.

The fingernails were short, friable, and thinned, except for the lateral one third of the right ring-finger. These findings were considered grade 4 nail changes (Clouston). The toenails were relatively narrow, irregular thick keratotic masses. The palms were erythematous, scaly, and fissured, and the dermatoglyphics, though barely discernible, were present and not unusual. The fingertips were broad and thickened and showed fine pebbling of the print lines. In several areas the tiny white orifices of the eccrine pores in the centers of the pebble papules could be seen easily with the naked eye.

A striking feature was the presence of globose erythematous papules and tumors on the insteps, ankles, and wrists with smaller lesions on the dorsal surfaces of the toes, calves, and forearms (Fig 2 to 4). The lesions measured 1 to 4 mm in diameter and up to 3 to 4 mm in height; they were smooth, soft, and erythematous and separated by deep crevices. Solitary lesions were seen on the thighs, buttocks, and abdomen. Numerous keratinous spines, resembling comedones, were also noted on the thighs and arms.

Eye examination showed bilateral corneal opacities. Results of the remainder of the physical examination were noncontributory.

Examination of the surface with a capillary microscope revealed vellus hairs on the scalp and markedly reduced numbers on the proximal portions of the extremities. They were absent from the distal portions of the extremities. A normal relationship between hair follicle and surface topography was preserved on the head, neck, and trunk to the waist. Patent and plugged follicles were evident at the junctions of the skin furrows. Occasionally spiny structures occupied the follicles. These could easily be extracted with a fine needle. The plug was soft, tooth-like, and occasionally contained a fine vellus hair. Interspersed throughout this pattern were almost invisible eccrine pores, revealed by bromphenol blue stain when the patient was heated.

The wrists and feet had a broad range of lesions from prominent eccrine pores to vascular tumors with pore-like apical punctae.

Follicles could not be found on the lower parts of the extremities. The eccrine pore gradually became the dominant element, surrounded by a keratotic ring, and accentuated with a rich capillary loop network (Fig 5). In the tumor regions the globose lesions replaced all other features. Sweat secretion could be detected from the apexes as well as the furrows between the tumors. On the palms and flat plantar surfaces the pores were located regularly along the crests of the ridges.

LABORATORY INVESTIGATIONS

Results of the following laboratory tests were within *normal* limits: hemogram, ESR, SMA 12, AC and PC glucose, urinalysis, ECG, EEG, thyroid function tests, upper gastrointestinal series, and urinary amino acids. Vaginal smears showed no evidence of keratinization. Buccal smears showed intermediate and superficial cells without evidence of keratinization. Serum carotene level was 118 μg/100 ml (normal

Fig 8.—Sections of a keratotic papule from thigh. Hyperkeratosis, hypergranulosis, and acanthosis are noted. Sweat duct ascends through vertical axis of lesion, from eccrine gland below (hematoxylin-eosin, ×200).

Fig 9.—Melanin is absent from basal layer of tumor below arrows (DOPA stain, ×400).

100 to 200 μg/100 ml) and the serum vitamin A level was 41.0 IU (normal 30 to 130 IU).

Results of the following laboratory tests were *abnormal:* skeletal survey showed dorsal kyphosis and slight scoliosis. Barium enema indicated diverticulosis along the transverse and descending colon. Immunoglobulin determinations on two occasions showed increased IgA of 550 to 750 mg/100 ml (normal 100 to 380 mg/100 ml).

HISTOPATHOLOGICAL FINDINGS

Sections of glabrous skin demonstrated no change in the surface epidermis with the exception of those in the cutaneous appendages described below. Melanocytes were demonstrated in normal distribution at the dermoepidermal junction.

In scalp sections the pilosebaceous units were small, superficial, and reduced in numbers. The hair follicles were dilated and filled with keratin. Prominent hypergranulosis was noted at the follicular orifices. The sebaceous glands were normal in distribution and morphology, as were the eccrine glands, except that the eccrine acrosyringia appeared hypercellular.

Sections from the axillae showed normal active apocrine glands, sebaceous glands, and occasional vellus hairs in cross section. A few eccrine ducts present on the section showed hypertrophic walls.

Examination of numerous tumors excised from the feet and wrists revealed a consistent picture (Fig 6) of absolute and relative hyperkeratosis. The underlying granular layer was prominent. Thick, anastomosing tracts of uniform cuboidal cells with preserved intercellular bridges proliferated into the dermis. Many were penetrated by dilated spiraling ducts lined with an eosinophilic cuticle and often containing eosinophilic material. The tumors were embedded in a highly vascular collagenous stroma. Islands of angioectatic stroma were seen within the tumors. Melanin was not demonstrated within the tumors either by DOPA or Fontana stains. Cells in the upper half of the tumor stained with PAS. The cuticle of the duct-like spaces was PAS-positive, diastase resistant. Centered under each tumor and in continuity with it were seen sections of eccrine ducts, which descended through the dermis to morphologically intact eccrine coils (Fig 7).

Sections of a keratotic papule, or "eccrine pseudohair," from the thigh showed a surface projection, consisting of a stratified column of hyperkeratosis, through the vertical axis of which ran a narrow duct (Fig 8). Under this hyperkeratosis the granular layer was 10 to 12 cells thick and the keratohyalin granules were very large. The acanthotic mass below consisted of cuboidal cells that extended into the dermis and was permeated by duct-like spaces lined with eosinophilic cuticle. These ducts were in continuity with the transcor-

neal duct above and with normal appearing eccrine ducts and glands below. Fontana and DOPA stains failed to reveal melanin in this lesion (Fig 9).

COMMENT

The salient clinical and histological features of this case were the profuse epithelial tumors of acral distribution and hidrotic ectodermal dysplasia. The evidence that the tumors were of acrosyringeal origin is as follows:

Clinical Findings

The tumors occurred in the distribution of eccrine syringia in proportion to the normal distribution of sweat glands in the involved regions. On capillary microscopy each of the tumors had a pore. Thermal sweat was produced by the tumors as detected by bromphenol blue dye.

Histological Findings

Eccrine ducts and coils were invariably associated with the tumors. The tumors contained ducts lined with PAS positive, diastase resistant material, typical of the lining of eccrine sweat ducts. The cells of the tumors had a uniform cuboidal appearance, and the prickles were preserved. The PAS-positive material was present in the tumor cells as it is in the case of eccrine poromas. Melanin was not found in the tumors, although it was present in the epidermis immediately adjacent to the tumors. This is typical of eccrine poromas,[7] although melanin has been observed in some cases.[8] Capillary ectasia and fibrosis surrounded the tumor. This is typical of eccrine poromas.

Sanderson et al[9] referred to benign solitary tumors arising from sweat duct epithelium as eccrine acrospiromas and they divided them into three types: intraepidermal (hidroacanthoma simplex), juxtaepidermal (eccrine poroma), and intradermal (dermal-duct tumor). They concluded there was no indication that heredity or external agents caused these tumors. Our patient had a spectrum of lesions, from eccrine pseudohairs, which are probably the product of hyperplasia and hyperkeratosis of the intraepidermal sweat duct unit, to juxtaepidermal lesions and intradermal tumors.

Pinkus et al[7] presented the first description of eccrine poroma of the solitary type. Goldner[10] reported the first case of multiple eccrine poromatosis in a 65-year-old woman, whose tumors affected the palm and the soles in circumscribed areas for 20 years. They were not associated with other abnormalities. The poromas in our case involved other parts of the extremities besides the palms and soles, and are diffuse in distribution. We consider this a different type of process from that described by Goldner, and suggest the term eccrine poromatosis to emphasize the diffuse nature. The presence of eccrine poromatosis in HED offers some difficulties in the conceptualization of pathogenesis. The abnormalities in this patient might stem from a single gene defect. Therefore eccrine poromatosis with hair and nail defects could represent the full expression of HED. In favor of this are the following points: (1) In many of the published cases of HED, pebbling was noticed over the acral areas in the distribution of eccrine glands, but was not examined histologically. (2) Abnormally dilated sweat ducts were noticed by Clouston.[1,2] (3) Our patient has features of the most severe expression of HED. (4) Our patient's sister, with severe HED, was reported to have similar tumors and HED findings. However, she was not available for examination.

The sporadic association of poromata and HED should also be considered. Evidence for this is as follows: (1) the absence of published cases of proven sweat gland tumors associated with HED, and (2) the onset of tumors after 40 years of age. This late onset is reported in sporadic cases of solitary and multiple nonsymetrical poromatosis.

Gold[11] proposed that abnormalities in hair keratin in HED is due to mutation of a single gene for matrix polypeptide. This leads to a deletion of a low sulfur segment of this polypeptide causing destabilization of intermolecular disulfide bonds in keratin. Could a defective gene for matrix keratin lead to development of acrosyringeal tumors and deletion of hair follicles in acral areas?

It is of interest that the sebaceous and apocrine glands showed no defect in their ductal structure, while the hair components of the follicle were markedly defective.

Squamous cell carcinoma of the nail bed and palms has been reported in HED.[4] Increased mitotic figures in poromata were also seen. The presence of eccrine acrosyringeal hyperplasia, though histologically benign, warrants regular medical supervision.

The investigation was supported in part by grant MA-3075 from the Medical Research Council of Canada.

Frederick Kalz, MD, referred this patient for investigation.

Phenytoin-Induced Pseudolymphoma Syndrome

An Immunologic Study

Maj Ernest N. Charlesworth, MC, USAF

• In vitro and in vivo immunologic studies were performed on a 28-year-old woman with phenytoin sodium-induced pseudolymphoma syndrome. During the acute phase of the syndrome, the patient appeared immunologically depressed. Six months after resolution of lymphadenopathy, repeat studies demonstrated a return to immunologic competence. In vitro studies of the patient's lymphocytes when incubated with phenytoin failed to indicate a delayed hypersensitivity reaction to the drug. These findings suggest that the patient developed a clinical lymphatic proliferation at a time when she was immunologically depressed. This may result in an increased chance of a mutant malignant clone developing at a time when the immunosurveillance system is impaired and explains why a rare patient with this syndrome may develop a frank malignant lymphoma.

Since the introduction of phenytoin in 1938 by Merrill and Putnam, numerous adverse reactions to the drug have been reported.[1,2] The most common dermatologic reaction is a morbilliform eruption occurring in 2% to 5% of patients; however, other types of dermatitis, including erythema multiforme and exfoliative dermatitis, can occur.[3] Phenytoin has been shown to cause a pseudolymphoma syndrome characterized by a generalized erythematous macular skin eruption, generalized lymphadenopathy, hepatosplenomegaly, fever, arthralgias, abnormal liver function tests, eosinophilia, and occasionally true lymphoma.[4-10]

An immunologic study of a patient with phenytoin sodium-induced pseudolymphoma syndrome was undertaken in an attempt to determine if patients with this syndrome have a depressed immunologic response.

REPORT OF A CASE

A 28-year-old black woman was discharged on a regimen of 300 mg of phenytoin sodium for treatment of an idiopathic seizure disorder. After six weeks of medication, she developed a severely pruritic generalized erythematous macular eruption, arthralgia, and diffuse lymphadenopathy. She was admitted to the Dermatology Service, and the medication was discontinued with no subsequent seizure activity.

Admission laboratory studies disclosed the following values: WBC, 6,500/cu mm, with 24% eosinophils; an elevated SGOT of 126 units (normal is 6 to 40 Karmen units); serum alkaline phosphatase of 26 units (normal is 4 to 13 King-Armstrong units), and a normal serum bilirubin level. A right cervical lymph node biopsy specimen showed reactive hyperplasia. A blood level of phenytoin drawn two weeks after discontinuation of the drug showed no detectable drug.

The patient was treated with 25 mg of hydroxyzine hydrochloride every six hours and topical 0.1% triamcinolone acetonide with resolution of the skin lesions and the pruritus.

MATERIAL AND METHODS

Acute Phase Testing

This phase of the testing was done at a time when there was no detectable blood level of phenytoin, when substantial lymphadenopathy was present. These studies consisted of both in vivo and in vitro testing.

In Vivo Acute Phase Tests.—All delayed hypersensitivity skin tests were done by the Allergy Department and included 0.1 ml of tuberculin purified protein derivative (5 TU/0.1 ml; Connaught Labs), histoplasmin (0.1 ml of a 1:100 concentration; Parke-Davis Co), coccidioidin (1:100 concentration diluted to 1:1,000; Bioproducts Iatric Corp), trichophyton (1:10 weight by volume [W/V] diluted to 1:500; Holister-

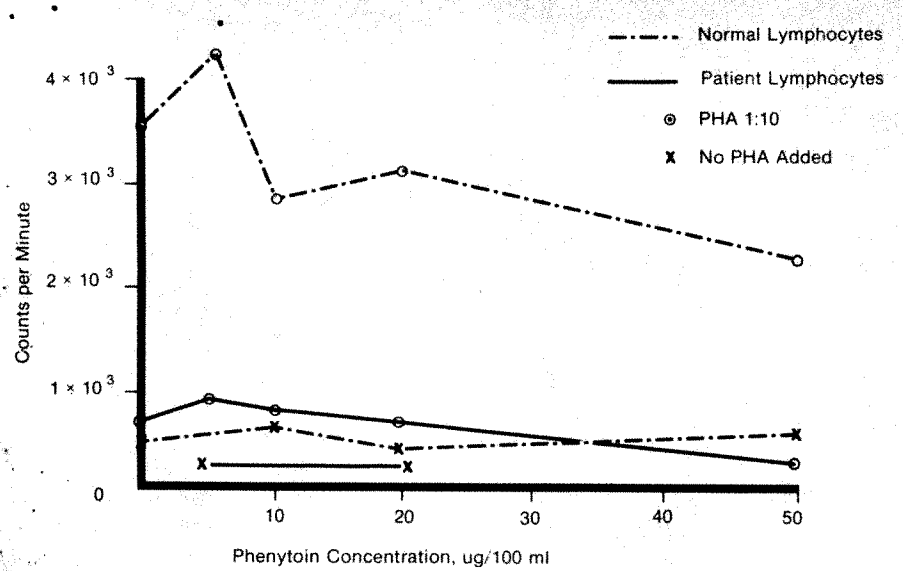

Fig 1.—Lymphocyte response to phytohemagglutinin and phenytoin. Patient was clinically symptomatic and anergic by skin tests to common antigens.

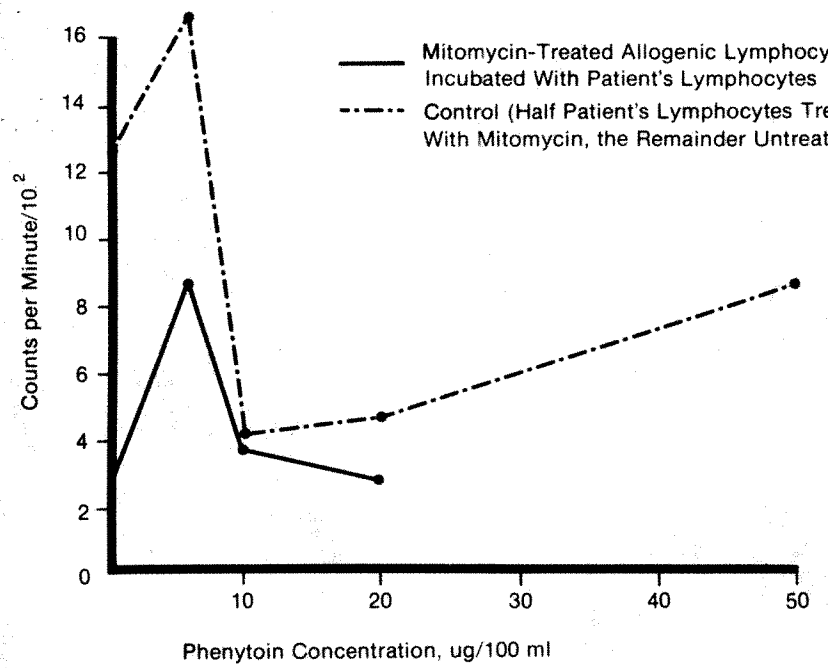

Fig 2.—Results of mixed lymphocyte reaction.

Stier Lab), mumps antigen; Lilly, and *Candida albicans* (1:10 W/V diluted to 1:500; Holister-Stier). Immunization with 0.5 ml of *Salmonella typhi* vaccine (typhoid bacilli 1,000 million/ml (Lilly) was attempted after drawing blood for baseline titers. All of these in vivo tests were initiated two weeks after the phenytoin had been discontinued.

In Vitro Acute Phase Tests.—All in vitro lymphocyte studies during the acute phase were done in the renal transplant immunology laboratory. A modification of the method of Senegar and Terasaki was used to study the response of peripheral blood lymphocytes to stimulation by phytohemagglutinin (PHA) and phenytoin.[11] Venous whole blood mixed with 100 units of heparin per milliliter was centrifuged. One milliliter of buffy coat and RBCs was recentrifuged in a polystyrene tube. The second buffy coat was mixed with 0.4 ml anti-H (prepared in the renal transplant laboratory from commercially obtained *Ulex europaeus* seeds) to remove RBC antigens. This was agitated for five minutes. The lymphocytes were purified by centrifugation and were concentrated on Ficoll-sodium diatrizoate gradients. The interface was removed and was washed with a culture medium of 10 ml of medium 199 (Difco), 14 ml of HEPES, 1.2 ml of penicillin-streptomycin solution (10^5 units of penicillin and 10 mg of streptomycin), and distilled water adjusted to 100 ml. To this, 20% of either pooled normal serum or the patient's serum was added to designated concentrations of phenytoin or PHA. After incubation for 96 hours at 36 C, the cells were pulsed with tritiated thymidine. After an additional 16 hours of incubation, the cells were harvested according to the method of Hartzman et al.[12] The vials were counted for ten minutes in a liquid scintillation spectrometer.

All mixed lymphocyte cultures were done in triplicate. Stimulating lymphocytes were treated with mitomycin to prevent DNA replication according to the method described by Bach and Voynow.[13] Such treatment prevents the cells from undergoing blastogenesis while enabling them to act as stimulating cells. This rendered the cells incapable of division and achieved a one-way mixed lymphocyte culture. The remaining procedures have been described previously.

Convalescent Phase Testing

This phase of the study was undertaken six months after all clinical evidence of the pseudolymphoma syndrome had resolved. These studies were divided into in vivo and in vitro testing as during the acute phase.

The same skin test antigens and concentrations for in vivo convalescent phase tests were applied as during the acute phase testing. When in vitro convalescent phase tests were attempted, the renal transplant immunology laboratory was unavailable to repeat the PHA and mixed lymphocyte cultures because of temporary technical problems. The convalescent PHA testing was done in the clinical research laboratory.

Seventy-two-hour tissue cultures of peripheral lymphocytes were evaluated according to the protocol of Claman and Brunstetter[14] with the following three modifications: 0.5×10^6 lymphocytes were used instead of 1.0×10^6 lymphocytes; 20% heat-inactivated human serum was used instead of fetal calf serum; and three dilutions (0.1 ml of 1:1, 1:10, and 1:25 of stock PHA solution) were tested with each culture. A terminal three-hour pulse of tritiated thymidine was used to evaluate the stimulatory response of the lymphocytes from the 69th to the 72nd hour of tissue culture. A separate set of cultures using various concentrations of phenytoin

Lymphocyte Response (Six Months After Convalescence)		
Substrate*	Patient, Counts/min	Control, Counts/min
Normal saline	574.8	1,108.1
PHA 1.00	173,871.8	167,138.2
PHA 0.10	389,909.7	379,766.8

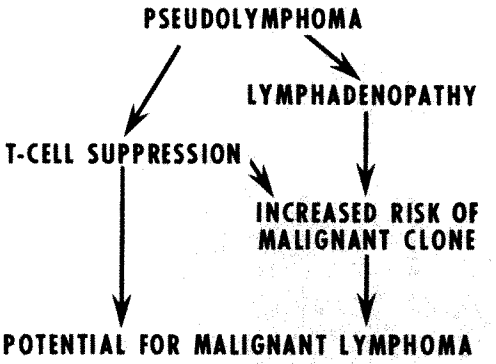

Fig 3.—Hypothesis for development of lymphoma.

were also done. All studies were done in triplicate, and normal saline was used as the control.

RESULTS

During the acute phase, the patient failed to show any reactions to the applied skin test antigens. The patient also failed to demonstrate a rise in typhoid O, typhoid H, or paratyphoid antibodies in four weekly serum samples after an initial immunization with *S typhi* vaccine. The effects of PHA on the patient's lymphocytes and the effect of various concentrations of phenytoin on the lymphocytes are shown in Fig 1. The graph shows no lymphocyte response to PHA or to phenytoin when compared with the matched control. The higher concentrations of phenytoin inhibited blast transformation and thymidine incorporation by the patient's lymphocytes. When the control and patient curves (Fig 1) were compared by statistical analysis, the results were highly significant ($P < .001$). This confirmed the incapability of the patient's lymphocytes to respond to either PHA or phenytoin. The failure of a lymphocyte response to phenytoin would not support this syndrome being a type IV[15] delayed hypersensitivity reaction to the drug.

The results of the mixed lymphocyte reaction done at the same time during the acute phase as the previous PHA testing are shown in Fig 2. The patient's lymphocytes showed a suppressed response to stimulation by the lymphocytes of an unrelated person that were viable but rendered nonresponsive by mitomycin. When the two curves (Fig 2) were subjected to statistical analysis, the P value was .1, indicating a 10% chance of random occurrence. While supporting the concept of the inability of the patient's lymphocytes to undergo blast transformation, it lacks the strong statistical significance of the acute phase PHA study.

The results of in vivo convalescence intradermal skin testing showed that the patient reacted with 6 mm of erythema to mumps and 8 mm of induration with 12 mm of erythema to *C albicans* at 24 hours. At 48 hours, she reacted to mumps with 12 mm of erythema and to *C albicans* with 9 to 10 mm of induration. The results of an in vitro study that was performed six months after complete convalescence are given in the Table. At this time, the patient's lymphocyte response to PHA was comparable to that of the normal control lymphocytes. Phenytoin showed no increased uptake of tritiated thymidine in either the patient's lymphocytes or the control lymphocytes. The lack of lymphocyte blast transformation in any of the concentrations of phenytoin indicates that the pseudolymphoma syndrome may not be a delayed hypersensitivity reaction.[16,17]

COMMENT

The present patient has the clinical syndrome that has been associated with phenytoin-induced pseudolymphoma. The histologic features of the lymph node and the lack of neoplastic evolution would place the patient in the "hyperplasia" group of pseudolymphoma as classified by Gams et al.[9]

The cause of this unusual reactive phenomenon remains obscure. Holland and Mauer[15] published data that demonstrated in vitro lymphocyte blast transformation in a patient with the pseudolymphoma syndrome attributable to phenytoin. They concluded that this syndrome may represent a delayed hypersensitivity reaction. Sorrell et al[19] studied 63 patients on long-term phenytoin therapy who had no evidence of any type of drug reaction. They found depression of in vitro lymphocyte transformation by PHA in .07%, absence of a delayed hypersensitivity reaction (type IV reaction)[15] to common antigens in 22%, and the failure of an antibody response to *S typhi* antigen in 9%. MacKinney and Booker studied patients with reactions to phenytoin and showed that the drug depressed DNA synthesis in cultured lymphocytes as measured by thymidine incorporation.[20]

The studies performed in the present case failed to show in vitro stimulation of the patients' lymphocytes by phenytoin. This does not support the concept of the pseudolymphoma syndrome resulting from delayed hypersensitivity reaction (type IV reaction).[15] The study fails to support the earlier findings of Holland and Mauer

and suggests that further studies are needed. The failure to elicit an antibody response to *S typhi* antigen suggests that the humeral immune-response may also be depressed, as well as the cell-mediated immunity, which corresponds with the data by Sorrell et al.[19]

An interesting hypothesis that attempts to explain the increased risk of lymphoid malignancy in diseases of depressed immunity has been proposed by Gershwin and Steinberg.[21] They have suggested that certain diseases, such as ataxia telangiectasia, the Wiskott-Aldrich syndrome, and the phenytoin-induced pseudolymphoma syndrome, may have an increased propensity to malignant transformation because of the loss of a normally occurring T-cell suppression. They suggest that this loss of T-cell suppression could result in the unregulated lymphatic proliferation favoring the development of a mutant clone of malignant cells. In this setting of depressed immunologic response, the body's immunosurveillance system may be unable to cope with the development of a malignant clone, resulting in a true lymphoma (Fig 3).

The studies presented here suggest that an immunologic hyporesponsiveness may exist in patients with pseudolymphoma induced by phenytoin during the period of lymphoproliferation. This may spontaneously abate when the medication is discontinued or may, in a rare patient, develop into a malignant lymphoma. This study adds credence to the hypothesis that certain diseases, including pseudolymphoma, may predispose the patient to the development of a frank malignant lymphoma when a proliferative lymphadenopathy is present in conjunction with an altered immunosurveillance system. These findings indicate that patients with this reaction to phenytoin need to be studied further before any firm conclusions can be drawn.

Lt Col Robert London, MD, and Sgt Ted Ball, MS, performed the technical studies during the acute phase. Lt Col Frank Brunstetter, MD, performed the convalescent phase testing.

Hidrotic Ectodermal Dysplasia

Study of a Large Chinese Pedigree

Krishna Rajagopalan, MB, MRCP, DDM, Chong Hai Tay, MB, FRCP

• Hidrotic ectodermal dysplasia was found, to our knowledge, for the first time in a Chinese family in Malaysia, and it affected 15 members in five generations. The disease, which is transmitted as a non-sex-linked autosomal dominant trait, presumably originated from southern China. All 15 members had the typical nail, hair, and skin lesions, and we observed three different types of nail defects. Scalp alopecia was more extensive in the female members, while keratoderma of the palms and soles was more notable in the male members. The nail and skin lesions also became severer with age. Except for the infectious eczematoid dermatitis present in the propositus, none had other skin or systemic disorders. All were relatively healthy and had normal life expectancies.

(*Arch Dermatol* 113:481-485, 1977)

Hidrotic ectodermal dysplasia (HED) is an uncommon autosomal dominant genodermatosis that is characterized by dystrophy of the nails, defects of the hair, keratoderma of the palms and soles, and, in a few instances, the presence of sensorineural deafness, polydactylism, syndactylism, mental retardation, and dwarfism.[1-4] In contrast to the anhidrotic ectodermal dysplasia, which is a sex-linked recessive condition, patients with HED have normal sweating, normal facies, and no specific dental abnormalities or an increased susceptibility to infections.

Although it is rare, this disease has been reported in many Western countries, in particular, Canada, where several families with large pedigrees have been described.[1,5-7] To our knowledge, the disease has not been previously reported in Asians. We describe a clinical study of a Chinese family from Malaysia with 15 affected members in five generations.

REPORT OF A CASE

A 28-year-old Chinese man was admitted to General Hospital, Johore Bahru, West Malaysia, for one week for treatment of extensive acute infectious eczematoid dermatitis (Fig 1). In the past, he had had a patch of lichen simplex chronicus on the left ankle, which was treated periodically with topical creams for about a year. For years he had been allergic to prawns, beef, mutton, aspirin, and certain seafood and had avoided these substances.

Since birth, his parents had observed that his nails, scalp hair and the skin of his hands and feet were abnormal. The nails of all of his fingers and toes rapidly became thick and discolored, and they were easily damaged at the edge by trauma or were infected around the nail folds. The badly damaged nails were often replaced by other imperfectly formed nails. The hair on the scalp, eyebrows, and eyelashes had remained sparse since infancy, although there was no excessive hair loss, increased hair brittleness, or abnormal color changes. He seldom shaved. For no apparent reason, too, the skin of his palms and soles gradually thickened and turned yellow. Cutaneous sensation and sweating, however, remained intact, Other than the previously mentioned cosmetic disfigurement that did not bother him, his physical, mental, dental, and sexual developments were all normal. There was no past history of drug allergies, contact dermatitis, bronchial asthma, hay fever, chronic infections, syphilis, exposure to heavy metals or toxic substances, or any other important systemic disorder.

When he was examined, except for a temperature of 38.3 C, his mental functions and general appearance, including the facies, were normal for his age and sex. Systemic abnormalities were not detected; the substantial findings were confined mainly to the skin, nails, hair, palms and soles. Numerous discoid eczematous lesions of varying sizes were found on the earlobes, cheek, upper part of the chest wall, right inner thigh, groin, left thigh, and dorsum of left foot. There was no regional lymphadenopathy. In addition to the infectious eczematoid dermatitis, he had the classical lesions of HED.

Notable dystrophic changes were found in all of the nails of his fingers and toes. They were smaller and opaque white to yellow, and either the whole or the distal part of the nail plate was considerably thickened. The nails that were severely involved, eg, the great toes and the right middle finger, showed substantial onycholysis and were cone-shaped or triangular

Accepted for publication Feb 19, 1976.

Reprints not available.

(Fig 2). There was complete or partial shedding of the nails in the little toes. Less-affected nails were normal in size, but showed cracks and chippings at their edges and margins, as well as pits, linear striations, and ridges on their surfaces (Fig 3). In most nails, especially those that were severely affected, there was lifting up of the distal portion of the plates from the nail bed by several millimeters, thus allowing the accumulation of dirt and subungual debris. The skin of all of the affected fingers and toes were hypertrophied with tissue enlargement and with papillary furrowing of the periungual skin distal to the nail (Fig 2 and 3). There was mild alopecia with moderate thinning of the hair over the parietooccipital areas of the scalp, but there was no detectable scalp lesion. Likewise, the hair of his eyebrows and eyelashes, as well as that of the axillae and pubis, was scanty, shorter, and finer than normal. Microscopical examination and culture studies of these types of hair did not show any abnormality. The palms and soles were yellow; they were hyperkeratotic with accentuation of the creases, and there was callus-like keratoderma with small fissures present in both soles (Fig 4 and 5).

The skin on other parts of the body was normal in texture and color. Sweating was normal, and no dental or bony defects were observed.

Laboratory investigations showed normal blood and urinary findings. Results of a VDRL test for syphilis were negative, and results of a glucose tolerance test were normal. The pus from the infected skin lesions grew *Staphylococcus pyogenes* that was sensitive to all common antibiotics. For one week he received 1 gm of oral tetracycline hydrochloride daily together with 15 mg of oral prednisolone in divided doses daily. The eczematous lesions were bathed with potassium permanganate. The fever rapidly subsided, and the eczematoid dermatitis cleared up by the end of the week and he was discharged. Since he gave a history that many members of his family were similarly affected by the same nail, hair, and skin defects, they, too, were investigated.

FAMILY STUDY

Almost all of the members of this family, except those who were already dead or who had left Malaysia, were personally examined by one of us. As shown in Fig 1, another 14 members in the five generations in this family had HED. Four of them, however, were reliably reported, since they had died long ago (cases 1 and 2) or were no longer in the country (cases 5 and 6).

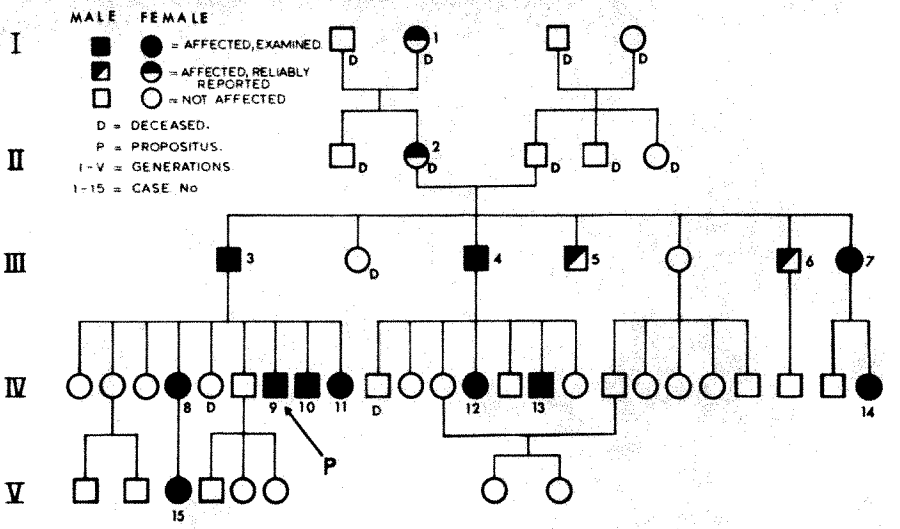

Fig 1.—Family pedigree. Arrow denotes propositus (P).

The numbers found in each of the five generations were 1, 1, 5, 7, and 1, respectively. It appeared that the disease originated from the propositus' paternal great-grandmother (case 1, generation I, who, with her daughter (case 2, generation II), were early immigrants from southern China. Both died of "old age" when they were 60 and 72 years old, respectively (Table). The family had lost track of their close relatives in China after the world wars, and it was impossible to trace whether other members were similarly affected by HED.

Inheritance

In this family, HED was transmitted as an autosomal dominant trait with almost complete penetrance. Half or almost half of the offspring from the affected members showed the classical lesions of the disease, while the unaffected members produced normal offspring. Even an intermarriage between two unaffected members in generation IV failed to transmit the disease to their two children.

CLINICAL FINDINGS

The detailed clinical findings of the 15 cases are listed in the Table. There were eight female members and seven male members, and their ages ranged from 1 to 72 years. The majority of them were in their third and fourth decades, and all were in good physical health. There were no premature deaths; the older members had perished from natural causes of death unrelated to HED. None had abnormalities of physical, mental, dental, or sexual developments. All had normal facies and sweating.

Nail Lesions

Practically all of the nails of the fingers and toes of those examined showed dystrophic changes of varying severity. Three types of defects characteristic of HED were observed. The commonest and most severe of all defects was the small cone-shaped or triangular nail found in the propositus, as well as in the older members of both sexes. Fingers and toes were affected with equal frequency. The second type of nail defect, sometimes is found together with the first in the same hand or foot. It consists of a normal-sized, moderately thickened plate, but the nail surface shows evidence of early dystrophy, eg, multiple grooves, pits, ridges, longitudinal striations, and/or irregular chips at the edges and sides. The propositus and most of the younger members (eg, cases 10, 11, and 13) had this form of nail lesion. The third defect was often seen in younger children and infants (eg, cases 14 and 15). The nail appeared smaller, but without much thickening, and was less convex in shape. The distal half of the plates was often separated from the nail bed by a gap at the center of the free edge. The nails of these children usually looked uncleaned, since dirt and other

*− indicates no lesion; +, mild lesion; + +, moderately severe lesion; + + +, severe lesion.

debris often filled the hollow space and could not be washed off easily.

Finger and Hand Lesions

In older members with the moderate and severe types of nail defects, the distal phalanges were thicker and wider than normal and also appeared clubbed because of tissue hypertrophy. The increased length of the rough, furrowed periungual skin looked as if it had displaced the affected nails proximally from the plump finger tips (Fig 2 and 3).

Hair Defects

Scalp alopecia in affected members varied from mild thinning (eg, in the propositus) to complete baldness (eg, cases 14 and 15). In some, alopecia appeared maximally soon after birth, and they remained bald throughout their lives, after shedding their lanugo hair. In the majority, hair loss was gradual and less severe, and occurred only after puberty. Female members, however, were more severly affected than male members, and most of them had to wear wigs. Men generally had scanty beards, and both sexes had sparse or total absence of eyebrows, eyelashes, and hair of the pubis and axillae. Macroscopical and microscopical examination of this hair showed no structural defects, brittleness, or pigmentary changes, but it was generally shorter, more downy, and finer than the normal hair.

Skin Lesions

Hyperkeratosis of the palms and soles were found in all of the members, except in the young. The thickness increased gradually with age. Those with severe hyperkeratosis and keratoderma had rough, dry skin with yellow callosities over the fingers. The palmar lines were deepened and prominent. The soles were usually more affected than the palms, and multiple small fissures developed in the keratodermal areas. As shown in the Table, the male members in this family generally had severer forms of keratodermal involvement than the female members. None, however, had developed malignant complications from these lesions.

COMMENT

Hidrotic ectodermal dysplasia is not excessively rare. The disease has been reported in a number of Western countries,[2-8] particularly Canada, where several large families of French or French-Canadian ancestries were discovered.[1,4-7]

The rarity of reported cases in Asians might be attributable to the lack of documentation or to the lack of awareness of the disease. Indeed, the milder forms of HED are easily mistaken for some commoner conditions. The present study of 15 cases in one Chinese family is probably one of the largest reported for this race.

As is classical of this disease, the transmission in this family was that of the non-sex-linked autosomal dominant trait, since almost half of the siblings of the affected members had the disease.[1,7] Normal members of the family rarely passed the disease on to their children, but skip generations have been reported.[5] Of interest was the intermarriage of two unaffected members in generation IV in this family; their offspring, as predicted by Wilkey and Stevenson,[6] in such a situation, were normal.

The disease in this Chinese family was traced to the propositus' great-grandmother, who was an immigrant from southern China. Although we were unable to trace her relatives in China, it would be assumed that this condition is also present in that part of the world.

In most studies, both sexes are equally affected, but a slight female preponderance was found in this study. Female members had a higher incidence of the severe form of scalp alopecia, while the male members suffered more from keratoderma. Persons of all ages were affected, since HED can appear initially either in infancy or, as found in our cases, soon after puberty.

We confirmed the observation made by Williams and Fraser[7] that the severity of the condition increases with age. This was particularly true for the nail and skin lesions. On the other hand, once the hair defect was present, it tended to remain unchanged throughout life. Earlier, Clouston,[1] using an elaborate point system, had argued that successive generations tend to have decreased severity of the disease. But when his cases were later reviewed, it was found that the severity was really related more to the age than to the diminished transmission in subsequent generations.[7]

Dystrophy of the nails, a key feature of HED, was found in all cases, but it is also well known that in 30% of those who are affected, especially young children, this lesion

might not be obvious.[5] This is because the nails in the young had slightly smaller nail plates that were not grossly thickened or deformed. The uplifting of the distal portion of the plate with the accumulation of debris between the nail bed and the nail may be minimal and may be mistaken for dirtiness, since these nails are difficult to keep clean. All three types of nail defects described by Wilkey and Stevenson[6] were found in our cases. The children's variety often changed into the adult types soon after puberty. Both the adult types of nail defects may be present in the same hand and foot. We found that the severer form affected the men more than the women. Part of the explanation might be because of the frequent trauma these brittle nails were subjected to.

Sparsity of the hair of the scalp, face, eyebrows, eyelashes, axillae, and genitalia also varied in severity in those who were affected. Substantial alopecia was encountered in two children (cases 14 and 15) and most of the female cases in this family. This cosmetic setback, however, did not prevent the affected female members from marriage, because they wore wigs and also drew in their eyebrows. The hair growth was slow and the shaft was fine and shorter than normal, but there was no apparent structural or pigmentary change. The third component of the syndrome, keratoderma of the palms and soles, was present in all but the youngest members of the family. Male members had a higher incidence of the severe form of this skin lesion. Others reported that skin thickening had spread from the palms to finger knuckles, knees, and elbows,[5] and that squamous cell carcinoma had developed from the keratosis on one occasion.[3]

Besides the infectious eczematoid dermatitis found in the propositus, the other affected members in this family did not demonstrate any skin lesions or congenital defects such as sensorineural deafness, polydactylism, syndactylism, or mild mental deficiency, as reported by others.[3-6]

In contrast to the anhidrotic ectodermal dysplasia, which is a sex-linked recessive disease, sweating was normal, and there was absence of anodontia, typical facies, dermatoglyphic abnormalities, hyperpyrexia, and tendency for recurrent infections. In the absence of a positive family history, one has to consider several differential diagnoses, such as congenital syphilis, pachyonychia congenita, nail-patella syndrome, familial tylosis, fungal nail infection, and psoriatic nail lesion.

The diagnosis of HED usually can be established by classical nail dystrophy in a patient with normal facies, no specific dental defects, normal sweating, and in the absence of other systemic or cutaneous involvement. Except for a single lethal case occurring in the homozygous state,[7] patients with HED, as shown in this and other family studies, generally have normal life expectancies.

Unilateral Nevoid Telangiectasia

Three New Cases and the Role of Estrogen

Jonathan K. Wilkin, MD

• Over a period of one month three patients attending a women's outpatient clinic at a general hospital were observed to have unilateral telangiectatic lesions. To our knowledge, only 12 cases of unilateral nevoid telangiectasia have been previously reported; this report would bring to 15 the number of cases of this syndrome. The temporal aspect of the onset of the lesions among these patients strongly supports the role of estrogen in the appearance of unilateral nevoid telangiectasia.

(*Arch Dermatol* 113:486-488, 1977)

Telangiectatic lesions have undergone several classifications, one of the most recent presented by Anderton and Smith.[1] The lesions are first divided into primary telangiectasia and telangiectasia presumably caused by, or associated with, other disorders. They classify unilateral nevoid telangiectasia syndrome as primary and include two subdivisions, viz, without systemic involvement and with systemic involvement. The latter subdivision was based on the very interesting case that they reported.

The following three intriguing cases led us to an examination of the previous reports of similar cases and the temporal aspects of the onset of this syndrome.

REPORT OF CASES

CASE 1.—A 17-year-old white primigravida, 18 weeks' pregnant by size and 22 weeks by dates, had an initial prenatal examination in May 1975. Telangiectatic lesions (Fig 1) were observed over the region of the scapula, extending along the posterolateral aspect of the arm, sparing the deltoid area and becoming somewhat anterior just above the elbow, but remaining lateral, and ending just below the elbow. The lesions were in a continuous distribution and were limited to the right side (Fig 2). The patient claimed that the telangiectases had been present for several months; and, although the area had not become larger, the lesions had become a brighter red. The patient denied previous lesions, previous exposure to oral contraceptives, bleeding or bruising tendency, and a family history of similar lesions. The patient did report that she had been treated for several weeks for infectious hepatitis in 1973.

Laboratory studies disclosed normal values for total protein, albumin, calcium, phosphorus, cholesterol, uric acid, creatinine, total and direct bilirubin, alkaline phosphatase, lactic dehydrogenase (LDH), SGOT, BUN, glucose, and electrolytes. Arterial blood gases while breathing room air showed pH 7.46, Po_2 99.9 mm Hg, and Pco_2 30.8 mm Hg, whereas after breathing 100% oxygen for a period of 15 minutes the values were pH 7.53, Po_2 558.0 mm Hg, and Pco_2 26.0 mm Hg.

A VDRL test for syphilis was nonreactive and a cervical culture for the *Gonococcus* showed no growth. The group and type was A-positive. A complete blood cell count revealed the following: hematocrit, 34%; WBCs, 11,300/cu mm; and platelet count, 325,000/cu mm. Prothrombin time was 13 seconds (control reading, 12.5 seconds).

CASE 2.—A 27-year-old white multigravida in the 26th week of pregnancy had an initial prenatal examination in May 1975. Telangiectases were noted in an area approximately 10 cm in length by 5 cm in width in the middle third of the right forearm on the extensor aspect (Fig 3). No similar lesions were noted elsewhere. The patient claimed that the telangiectasias had been present for several months; and, although the area had not become larger, the lesions had become a brighter red. The patient noted that this lesion appeared in the same manner and in the same location in each of three normal pregnancies in 1963, 1965, and 1972. Further, she claimed that the lesions disappeared within several weeks after delivery. The patient denied previous lesions, except for those during the previous pregnancies. The patient denied previous exposure to oral contraceptives, bleeding or bruising tendency, a family history of similar lesions, and a past history of jaundice, hepatitis, or other hepatic disorder. Laboratory studies disclosed normal values for total protein, albumin, calcium, phosphorus, cholesterol, uric acid, creatinine, total and direct bilirubin, alkaline phosphatase, LDH, SGOT, BUN, glucose, and electrolytes. Arterial blood gases while breathing room air showed pH 7.50, Po_2 98.6 mm Hg, and Pco_2 33.3 mm Hg, whereas after breathing 100% oxygen for a period of 15 minutes the values were pH 7.51, Po_2 530.0 mm Hg, and Pco_2 31.2 mm Hg.

A VDRL test for syphilis was nonreactive and a cervical culture for the *Gonococcus* showed no growth. The group and type was A-positive. A complete blood cell count revealed the following: hematocrit, 36%; WBCs, 11,600/cu mm; and platelet count, 315,000/cu mm. Prothrombin time was 11.5 seconds (control reading, 12.5 seconds.) Partial thromboplastin time was 36.4 seconds (control reading, 39 seconds).

CASE 3.—A 16-year-old white primigravida, ten weeks pregnant was evaluated for a voluntary abortion in June 1975. Telangiectatic lesions were observed in the area from the right preauricular area along the mandible to the right of the mentum to the origin of the sternocleidomastoid laterally to the acromion and medially along the posterior margin of the sternocleidomastoid. A small patch of telangiectases was also observed inferior to the clavicle and to the right side of the midline (Fig 4). The patient claimed that the lesions were first noted at 10 or 11 years of age and had not undergone any changes in size or color, until an increase in redness during the preceding month. The patient claimed that a maternal aunt had a similar lesion on her neck. The patient denied previous exposure to oral contraceptives, bleeding or bruising tendency, and a past history of jaundice, hepatitis, or other hepatic disorder. The patient's history was corroborated by her mother.

Laboratory studies disclosed normal values for total protein, albumin, calcium, phosphorus, cholesterol, uric acid, creatinine, total and direct bilirubin, alkaline phosphatase, LDH, SGOT, BUN, glucose, and electrolytes. Arterial blood gases while breathing room air showed pH 7.46, Po_2 112.1 mm Hg, Pco_2 30.0 mm Hg, whereas after breathing 100% oxygen for a period of 15 minutes the values were pH 7.45, Po_2

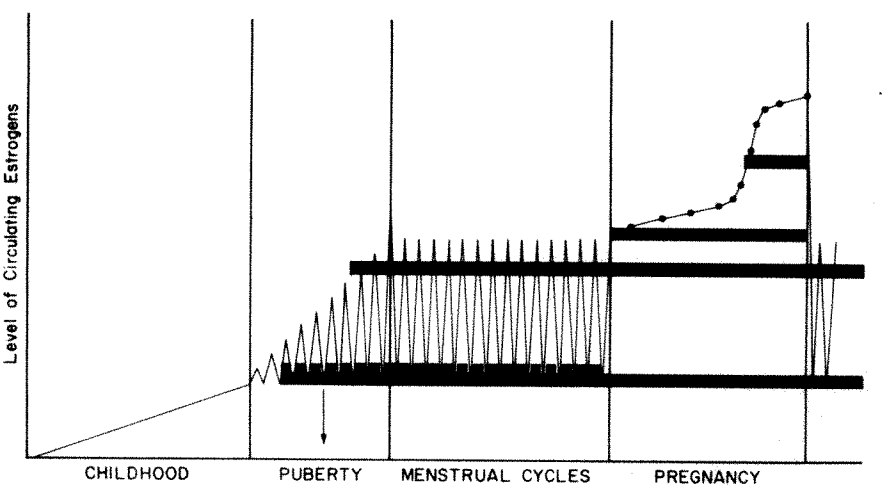
539.7 mm Hg, and P_{CO_2} 31.8 mm Hg.

A VDRL test for syphilis was nonreactive and a cervical culture for the *Gonococcus* showed no growth. The group and type was O-positive. A complete blood cell count revealed the following: hematocrit, 36%; WBCs, 6,400/cu mm; and platelet count 230,000/cu mm. Prothrombin time was 14 seconds (control reading, 13 seconds). Partial thromboplastin time was 35.5 seconds (control reading, 39 seconds).

COMMENT

The brief report of Zeisler[2] of a pregnant patient with scattered telangiectases in a unilateral distribution along the left arm and shoulder is perhaps the first recorded case of the unilateral nevoid telangiectasia syndrome. He noted that the lesions were present during pregnancy and disappeared thereafter only to return in a subsequent pregnancy. Tommasi[3] reported the onset of telangiectases in a unilateral distribution in a patient three years prior to onset of menses. Further, the lesions also became redder during the proliferative phase of the menstrual cycle. Bean et al[4] observed the appearance of vascular spiders and palmar erythema in normal pregnancies, noting the symmetrical scattering of lesions and postulating that increased estrogen may lead to the appearance of these lesions. Billings[5] reported the case of a pregnant patient who first noted unilateral telangiectases of the right hand and forearm in the fifth month of pregnancy that became brighter as the pregnancy progressed, although the area of skin involved did not increase. In the first week postpartum the lesions had faded, becoming very faint two months later and subsequently disappearing altogether. Bowen[6] had a patient in whom unilateral telangiectatic lesions appeared on the left side of the neck and left arm one year after the onset of menses.

Fig 5.—Temporal relationship between nevoid telangiectasia and level of circulating estrogens (arrow denotes menarche).



Selmanowitz[7] presented two cases of unilateral nevoid telangiectasia. In the first case the lesions appeared at puberty and had been present for seven years in a nonpregnant, 21-year-old woman. The telangiectases occurred on the left side of the face, the left portion of the neck, the left shoulder, the left supraclavicular and medial infraclavicular regions, and the lateral aspect of the left upper extremity terminating at the wrist. In the second case the telangiectases had been present in a 47-year-old man since birth in a similar distribution on the left side, except that the face was not involved and the lesions extended somewhat lower on the chest and on the dorsum over the left scapula. Aram and Solomon[8] reported two cases of telangiectasia in a unilateral distribution. The first patient was a 28-year-old gravida who had lesions on

Summary of Unilateral Nevoid Telangiectasia Syndrome Cases				
Case No.	Source	Sex	Condition Present at Onset of Lesions	Distribution
1	Zeisler[2]	F	Pregnancy	L; C-4,5
2	Tommasi[3]	F	Puberty	Unknown
3	Billings[5]	F	Pregnancy	R; C-2,3,6,7,8, T-2

15	Present study	F	Puberty	R; C-2,3, T-2

the right side of the chest, arm, and forearm. This was the second time she had lesions, having had unilateral telangiectases during her previous pregnancy, which faded postpartum. The second patient was a 25-year-old woman who received estrogen-progesterone compounds intramuscularly for menstrual disturbances prior to the appearance of telangiectases approximately five years earlier on the right anterior part of the chest, shoulder, and upper arm. Mirrer et al[9] reported the onset of telangiectatic lesions over the right side of the body; upper and lower extremities; and the central part of the face, nose, lips, and oral mucosa in a 52-year-old woman with cirrhosis of the liver, upper gastrointestinal bleeding, and a long history of alcohol abuse. Greer[10] presented a second case of unilateral nevoid telangiectasia developing in association with cirrhosis of the liver. The patient was a 54-year-old man who had telangiectatic lesions of the right anterior part of the chest of one month's duration prior to admission for alcoholic cirrhosis of the liver. Frankel[11] reported a third case of unilateral nevoid telangiectasia developing in association with alcoholism, although liver damage or findings of cirrhosis were not demonstrated. The patient was a 45-year-old man with a four-year history of telangiectatic lesions over the right part of the thorax and right arm; the patient admitted to increased alcoholic consumption during this time. Anderton and Smith[1] presented a 40-year-old man, the fourth reported case of alcoholic cirrhosis of the liver, who had telangiectases over the left trigeminal, C-3, C-4, C-5, and T-1 dermatomal areas that appeared nine years previously; also, endoscopy revealed scattered telangiectases over the entire gastric mucosa. Further, they reviewed some of the earlier information concerning the unilateral nevoid telangiectasia syndrome and presented a new classification of the telangiectatic syndromes.

With the exception of those cases of unilateral nevoid telangiectasia appearing in association with alcoholism (cases 9, 10, 11, and 12), the acquired cases seem to appear coincident with a physiologic state in which the level of estrogen is increased. This may be interpreted as circumstantial evidence that estrogen triggers the telangiectasia. Thus, the highest bar in Fig 5 indicates telangiectasia occurring only in the latter half of pregnancy when the highest levels of estrogen occur (case 3). In the same figure the second highest bar indicates telangiectasia occurring throughout pregnancy when estrogen levels are high (cases 1, 7, 13, and 14). Also depicted are case 4 in which the telangiectasia appeared slightly after menarche, and case 2 in which the telangiectasia appeared slightly before menarche and demonstrated proliferative phase reddening.

In 14 of the known 15 cases of unilateral nevoid telangiectasia syndrome the telangiectasia was acquired. In the only congenital case the patient was male (case 6). Of the acquired cases ten were unrelated to alcoholism, were exclusively female, and did not exhibit systemic involvement. The remaining four acquired cases were related to alcoholism, were predominantly male (three of four cases), and included the single case with systemic involvement. Thus, a subclassification of the unilateral nevoid telangiectasia syndrome may be proposed:

Unilateral Nevoid Telangiectasia
I. Congenital
II. Acquired
  A. Estrogen-related
  B. Alcohol/hepatic-related
    1. Without systemic involvement
    2. With systemic involvement

In summary (Table), three new cases of the unilateral nevoid telangiectasia syndrome have been presented, circumstantial evidence implicating estrogen in the onset of the telangiectases has been noted, and a subclassification of the unilateral nevoid telangiectasia syndrome has been suggested.

Secondary Syphilis Presenting as a Pruritic Dermatosis

Gary W. Cole, MD; Robert B. Amon, MD; Paul S. Russell, MD

• Three patients had secondary syphilis with severely pruritic skin lesions. This presentation contradicts several modern medical texts in which the lesions of secondary syphilis are described as nonpruritic.

(*Arch Dermatol* 113:489-490, 1977)

In a number of modern medical texts and recent articles, the cutaneous eruption of secondary syphilis has been described as nonpruritic.[1-6] Certain authors advise that the presence of pruritic skin lesions virtually rules out the diagnosis of secondary syphilis.[7] Recently, we diagnosed and treated three patients with secondary syphilis who presented with severely pruritic eruptions.

REPORT OF CASES

CASE 1.—A 42-year-old man first came to the Portland Veterans Administration Hospital in February 1975, with severe pruritus confined to his perineum. Nits were identified, and he was treated with benzene hexachloride, gamma. Following treatment, the patient's pruritus rapidly resolved.

Accepted for publication March 16, 1976.

From the Department of Dermatology, University of Oregon Health Sciences Center, Portland.

Reprint requests to University of Oregon Health Sciences Center, 3181 SW Sam Jackson Park Rd, Portland, OR 97201 (Dr Cole).

The patient returned two weeks later, again complaining of pruritus, but this time confined to his back, abdomen, and flexor forearms. He denied the presence of preceding genital, anal, or oral lesions. He also disclaimed any previous history of syphilis or recent antibiotic therapy. On physical examination, groups of excoriated papules localized to his back (Fig 1), forearms (Fig 2), and abdomen were present. No evidence of pediculosis or scabies was found. Except for generalized lymphadenopathy, the remainder of the physical examination was normal. Laboratory tests included a WBC of 5,100/cu mm with a normal differential. Values for hematocrit, alkaline phosphatase, SGOT, CPK, BUN, and urinalysis were all within normal limits. The VDRL test for syphilis was positive at a titer of 1:128. The FTA-ABS was also positive. The patient was treated with 2.4 million units of penicillin G benzathine, and the skin lesions and pruritus cleared within two days. He did not exhibit a Herxheimer reaction. During the ensuing six months, the patient's quantitative VDRL test for syphilis declined to a titer of 1:4 with no recurrence of pruritus.

CASE 2.—A 35-year-old man presented to the Portland Dermatology Clinic with a three-week history of an intensely pruritic skin eruption confined to his lower extremities, his perineum, and the palms of both hands. Some of these lesions were slightly scaly while others appeared nodular and erythematous. He denied any preceding genital or oral lesions. The patient had a normal CBC and a negative throat culture.

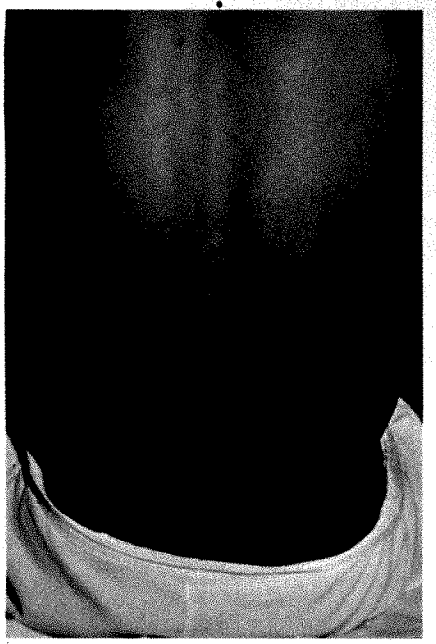

Fig 1.—Excoriated papules on lower back of patient 1.

Fig 2.—Papules on forearms of patient 1.

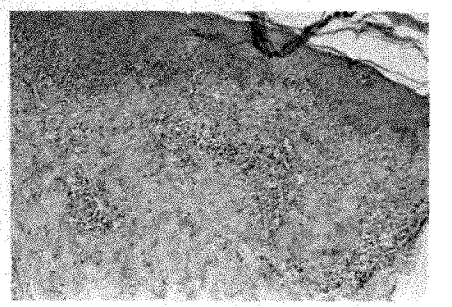

Fig 3.—Skin biopsy from patient 2 showing a mononuclear cell infiltrate in the dermis (hematoxylin-eosin, original magnification ×80).

The VDRL test for syphilis was positive at a titer of 1:64, and the FTA-ABS was positive. A skin biopsy was done (Fig 3) that showed liquifaction degeneration of the basal layer of the epidermis with a cellular infiltrate near the dermal-epidermal junction composed of histiocytes, lymphocytes, and plasma cells.

The patient was treated with 2.4 million units of penicillin G benzathine with subsequent resolution of his pruritus and skin eruption. He developed no Herxheimer reaction. His VDRL titer has shown a steady decline, and his pruritus has not returned.

CASE 3.—A 38-year-old woman was seen in early October 1975 in the Outpatient Clinics of the University of Oregon Health Sciences Center for menstrual cramps and a nondescript vulvar ulcer. No Darkfield examination was done, and a VDRL test for syphilis drawn at that time was nonreactive. The patient returned two weeks later complaining of a four-day history of an intensely itchy eruption over her entire body.

On physical examination, a generalized papular rash was present that also involved her palms and soles. Except for tender, inguinal lymphadenopathy, the remainder of the physical examination was normal. No vulvar nor oral lesions were present, and her pruritus was treated symptomatically with diphenhydramine hydrochloride. As part of the routine follow-up of the original vulvar ulcer, a VDRL test for syphilis and FTA-ABS were obtained. The VDRL was reactive at a titer of 1:32 and the FTA-ABS was positive.

The patient was treated with 2.4 million units of penicillin G benzathine. She noted no Herxheimer reaction, and her pruritic skin eruption resolved within four days. The patient's quantitative VDRL titer has shown a steady decline, and there has been no recurrence of her pruritic dermatosis.

COMMENT

In all of our patients, the presenting symptom of secondary syphilis was pruritus. In this manifestation of the "great imitator" so rare that the physician may feel secure that its presence virtually rules out syphilis? We think not. Conant[8] reported one patient with a papulonodular syphilid who itched slightly. Lockner and Pomeranz[9] reported three patients with "lichenoid" secondary syphilis who experienced some itching during their illness. All of our patients as well as two of Lockner and Pomeranz' were black. Stokes et al[10] referred to a follicular syphilid seen in black patients that may be pruritic. King and Nicol[11] described a pruritic, papular syphilid seen in patients with pigmented skins.

It is our intention to emphasize that pruritus as a presenting symptom in the presence of skin lesions suggestive of syphilis should not blind the physician to the possibility that *Treponema pallidum* may be the etiological agent. This appears to be especially true in darkly pigmented patients with papular syphilids.

Westwood Pharmaceuticals Inc supplied a grant that made possible the publication of the color reproductions.

Giant Melanosomes in Multiple Lentigines Syndrome

Larry W. Weiss, MD, PhD, Alvin S. Zelickson, MD

• **Biopsy specimens of normal skin and lentigines from an 82-year-old man with multiple lentigines syndrome were examined with light and electron microscopes. Giant melanosomes were found in dermal melanophages, melanocytes, and keratinocytes in all epidermal layers. Morphologic characteristics of these melanosomes are described, and other conditions in which they have been found are discussed.**

(*Arch Dermatol* 113:491-494, 1977)

Recently, giant melanosomes have been reported in the pigmented macules of neurofibromatosis[1,2] and in nevus spilus.[3,4] We studied biopsy specimens of normal skin and lentigines from a patient with multiple lentigines syndrome and found giant melanosomes in these latter sites by both light and electron microscopy.

REPORT OF A CASE

An 82-year-old man had generalized pigmented macules, which included the palms and soles, that apparently developed when the patient was a young child. Other findings included ocular hypertelorism, shortness of stature, kyphoscoliosis, pectus excavatum, bilateral partial sensorineural deafness, and an absent left testicle that was undescended and surgically removed at age 6 or 7. There were no clinically detectable cardiac abnormalities. Laboratory studies disclosed a leukocyte count of 3,900/cu mm and a hemoglobin level of 11.8 gm/100 ml. The ECG showed a first-degree atrioventricular block, a left axis deviation, and low voltage and posterior rotation. The patient has also had a malignant melanoma excised from the posterior aspect of his left ear in 1973.

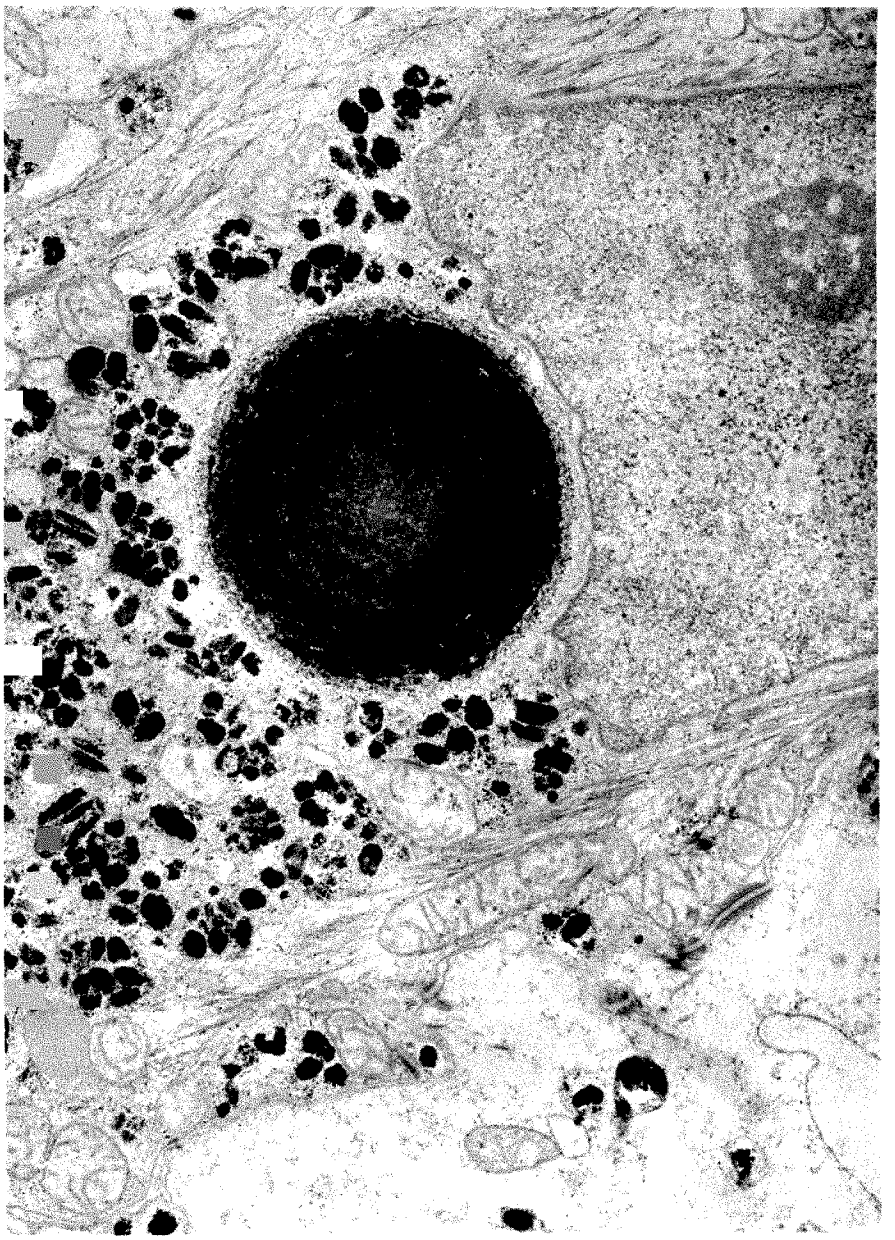

Fig 2.—This basal cell contains many normal melanosome complexes and one giant melanosome in which numerous vesicles, as well as concentric layers of varying electron density, are visible (original magnification ×17,400).

HISTOPATHOLOGIC FINDINGS

Punch biopsy specimens of normal skin and pigmented macules of the abdominal area were obtained for light and electron microscopical studies. The tissue for light microscopy was fixed in a 3.7% formaldehyde solution and was embedded in paraffin, and the sections were stained with hematoxylin-eosin. Specimens for electron microscopy were fixed in glutaraldehyde, postfixed in osmium tetroxide, and embedded in Spurr,[5] and the thin sections were stained with uranyl acetate and lead citrate.

Light microscopical studies showed proliferation of the epidermal rete ridges and an increased number of epidermal melanocytes. The basal layer contained large amounts of pigment, and giant melanosomes were present in focal areas throughout the epidermis, including the stratum corneum. A few giant melanosomes were also noted within dermal melanophages.

Ultrastructural studies also showed the presence of giant melanosomes within melanocytes and keratinocytes in the lowermost layers of the stratum corneum and in dermal melanophages (Fig 1). Numerous normal melanosomes were present principally within the melanocytes and basal cells. The normal melanosomes were generally aggregated into melanosome complexes within keratinocytes, whereas the giant melanosomes were singly dispersed, and there was rarely more than one giant melanosome within the same keratinocyte (Fig 2 and 3).

The giant melanosomes measured up to 5 μ in diameter and often indented the keratinocyte nucleus. These melanosomes were membrane-limited. At times the membrane was partially disrupted. Giant melanosomes within the stratum corneum often distended the cell cytoplasm, and no limiting unit membrane was observed (Fig 4).

Most of the giant melanosomes were spherical, and the internal structure was characterized by a dense central core of uniform electron density (Fig 3). Peripheral to the central core, there were more irregular electron-dense deposits and numerous electron lucent puncta that were

arranged in concentric layers. In the region just inside the limiting membrane, less electron-dense material was present, and the puncta were more easily visualized. Even in the fully melanized giant melanosomes that were present in keratinocytes, puncta were still visible in the outermost coritcal area of the granule. The filamentous substructure present in normal melanosomes was notably absent within the giant melanosomes, and no evidence of fusion of vesicles with giant melanosomes within the melanocytes was observed. The peripheral portions of giant melanosomes within the stratum corneum had some fragmentation, suggesting degradation.

COMMENT

Multiple lentigines syndrome is characterized by a variety of abnormalities and an autosomal dominant hereditary pattern of inheritance. The mnemonic "leopard syndrome" is often used to characterize many of the known abnormalities: lentigines, ECG conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness of the sensorineural type.[6] Our patient had all of these except pulmonary stenosis.

Ultrastructural studies of skin in patients with multiple lentigines syndrome have shown the presence of extensive normal melanosome complexes, but not the presence of giant melanosomes.[7] Recently published ultrastructural studies have shown that giant melanosomes are present in the pigmented or café au lait macules of neurofibromatosis[1,2] and in nevus spilus.[3,4]

At the light microscopical level, the giant melanosomes have been observed in keratinocytes and melanocytes in the normal skin of patients with neurofibromatosis, as well as in the pigmented macules.[8] They are rarely present in Albright syndrome[8] and in the nevus spilus.[3,4]

Ultrastructural studies indicate that the giant melanosomes are inherently electron dense and can be visualized without heavy metal staining or osmium tetroxide fixation (special stains were not used in our study).[2]

Fig 3.—Giant melanosome within this keratinocyte displays characteristic dense central core and concentric peripheral area in which melanization is incomplete (original magnification ×22,000).

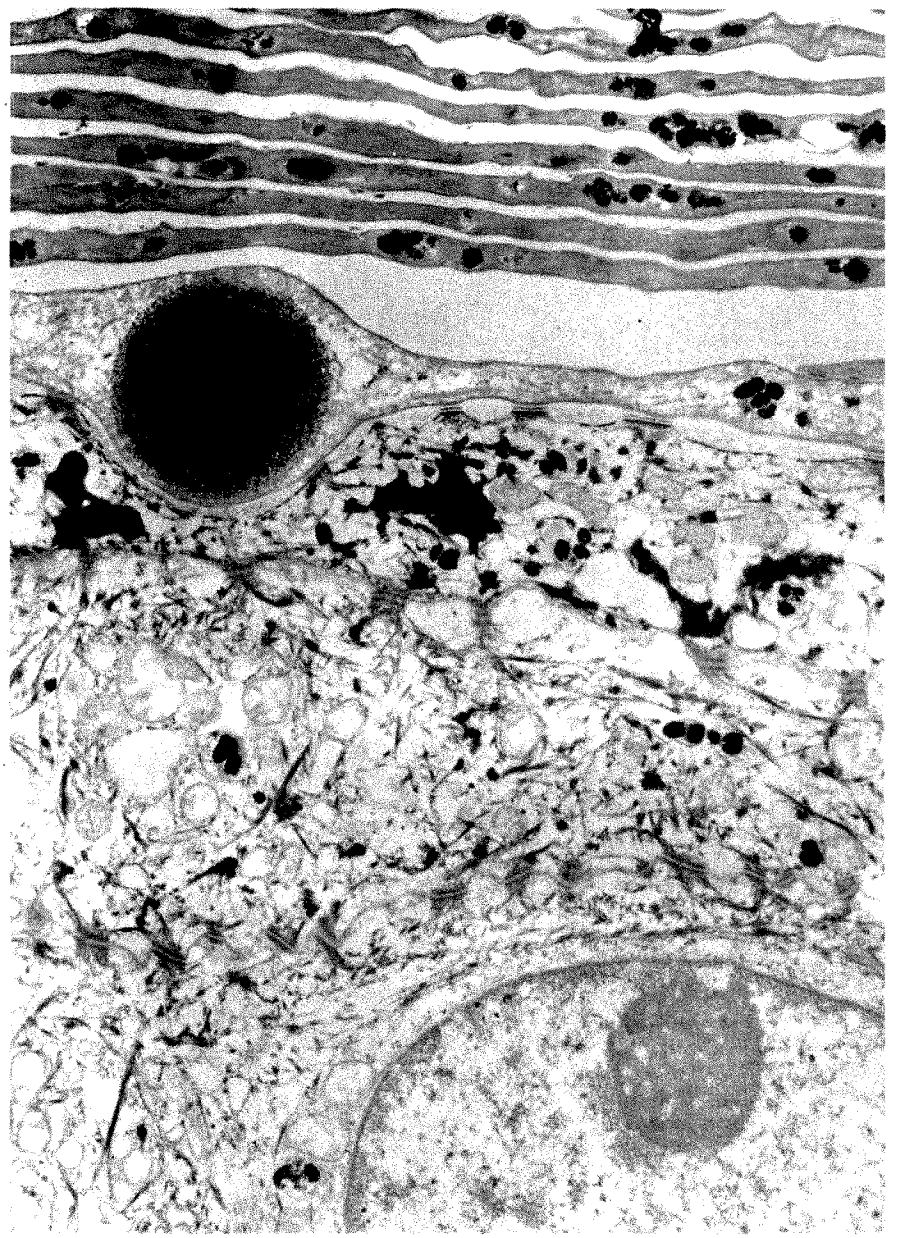

Fig 4.—Lowermost cell within stratum corneum contains giant melanosome that distends cell. Many normal melanosomes are also present within stratum corneum. Note absence of limiting membrane surrounding giant melanosome (original magnification ×13,600).

These melanosomes are also tyrosinase-positive after eight or more hours of incubation, but lack acid phosphatase activity.[3] Giant melanosomes may be classified as such in that they seem to be formed within melanocytes and exhibit tyrosinase activity, although the size as well as the vesicular rather than filamentous substructure do not agree with the classical features of normal melanosomes. Melanosomes in pigmented hair bulbs also demonstrate puncta similar to those in giant melanosomes, thus providing evidence for a further relationship.[3,9] The mode of giant melanosome formation remains elusive, but it has been suggested that a reasonable possibility may be by fusion of cytoplasmic vesicles that have been observed in the vicinity of giant melanosomes. However, such actual fusion has not been observed.[3]

The peripheral fragmentation and, at times, lack of limiting membrane surrounding giant melanosomes in the stratum corneum suggests that some degradation does occur. The individual dispersion of giant melanosomes is in agreement with previous studies, indicating that even normal melanosomes of a larger size tend to be singly dispersed.[10] It has been suggested that giant melanosomes form as a result of deranged morphogenesis, perhaps at the stage preceding the assembly of melanosomal filaments in which microvesicles may be involved.[3] Careful searches of specimens from various pigmentary conditions need to be made, now that there is increased awareness of the presence of giant melanosomes, so that new clues for their formation may possibly be uncovered.

Depressed Immune Function in Epidermodysplasia Verruciformis

Steven E. Prawer, MD; Franklin Pass, MD; James C. Vance, MD;
Leonard J. Greenberg, PhD; Edmond J. Yunis, MD; Alvin S. Zelickson, MD

• **Epidermodysplasia verruciformis (EV) is a rare disease characterized by the early onset and unremitting progression of wart-like lesions and frequent association of cutaneous carcinomas. We report two siblings with EV. Immunologic study of both patients demonstrated normal immunoglobulin levels, normal numbers of T-lymphocytes and B-lymphocytes, but markedly depressed in vitro blastogenic reactivity to mitogens and antigens. Cutaneous anergy to a variety of common skin test antigens was noted. These observations may reflect an inherited abnormality in immune function, or the depressed immune function may result from the viral infection of EV.**

(*Arch Dermatol* 113:495-499, 1977)

Epidermodysplasia verruciformis (EV) is a rare disease characterized by multiple wart-like tumors beginning in early childhood.[1] The wart-like tumors resemble flat warts both clinically and histologically, and virus particles have been observed repeatedly in electron microscopic specimens.[2] Warty lesions persist throughout life and are often associated with epithelial carcinomas in early adult life.[3] The disease often occurs in several members of a family, so EV has been classified as a genodermatosis.

We wish to report two siblings with characteristic EV. Both patients displayed depressed immune function as indicated by anergy to multiple skin tests and depressed blastogenic reactivity in vitro. This may represent an inherited defect in immune function, which predisposed the patients to widespread cutaneous viral infection and viral carcinogenesis, or conversely, the widespread viral infection caused a depression of their immune function.

REPORT OF CASES

Case 1.—A 43-year-old woman was first seen in March 1975, for evaluation. Before age 10, she began to develop wart-like lesions over the dorsum of her hands, and over the years, many similar lesions appeared elsewhere. In 1974, a squamous cell carcinoma was excised from her right cheek. In March 1975, lesions removed from her left wrist and right second finger showed varying degrees of irregular epithelial growth and dyskeratosis compatible with an actinic keratosis and squamous cell carcinoma in situ. The patient was in otherwise good health.

Examination showed many discrete and some confluent papular lesions which resembled warts. Individual lesions were grey to tan, slightly elevated, and ranged from several millimeters to 1 cm in diameter (Fig 1). Lesions occurred in a generalized distribution, but the dorsum of her hands, the extensor surfaces of her forearms, the area around her knees, and her neck were most heavily involved. Many of the lesions were less raised and deeper tan with a wrinkled scale. Evidence of prior surgical procedures was noted. None of the lesions present showed ulceration or inflammation.

The patient's mother had died at age 49 after a prolonged hospitalization for pulmonary disease in 1953. Her medical records have been misplaced, but a report of her autopsy was located. It described multiple warts on her hands and arms and pulmonary nodules that contained yeast-like organisms. No identification of the organisms in the lungs nor biopsy of the skin lesions was recorded. The patient's father and one sibling were deceased. Three siblings including the female twin of case 2 were alive, well, and free of warts. The patient had four children and four grandchildren. One grandchild had several common warts on his fingers.

Case 2.—A 39-year-old male sibling of the patient in case 1 was first examined in April 1975. He recalled having wart-like lesions before the age of 9. He continually developed additional lesions, but no malignancy had occurred. His general health was good. He had not married and had no children.

Examination revealed multiple lesions over the dorsum of his hands, forearms, legs, and neck. Lesions on his hands resem-

Dermis contains chronic inflammatory infiltrate (hematoxylin-eosin, original magnification ×400).

bled flat warts, but many of the lesions on his neck and knees seemed broader, less elevated, scaly, and pigmented (Fig 2). No evidence of malignancy was observed.

MATERIALS AND METHODS

Biopsies were performed on wart-like lesions from both patients. Specimens were embedded and sectioned for light microscopy in a routine fashion and stained with hematoxylin and eosin. Biopsy specimens taken of wart-like lesions from both patients were fixed in 2.5% gluteraldehyde, rinsed in sodium cacodylate buffer (pH 7.4), and postfixed in 1% buffered osmium tetroxide. Specimens were embedded in epoxy resin and stained with uranyl acetate and lead citrate. Sections prepared with an ultramicrotome (LBK) were examined with an electron microscope (RCA).

Venous blood was collected from the patients in sterile heparinized syringes. Blood was also collected from the 40-year-old sister of the patients, the 22-year-old daughter of patient 1, and three normal young adult men, who were to serve as reagent controls for in vitro studies. An

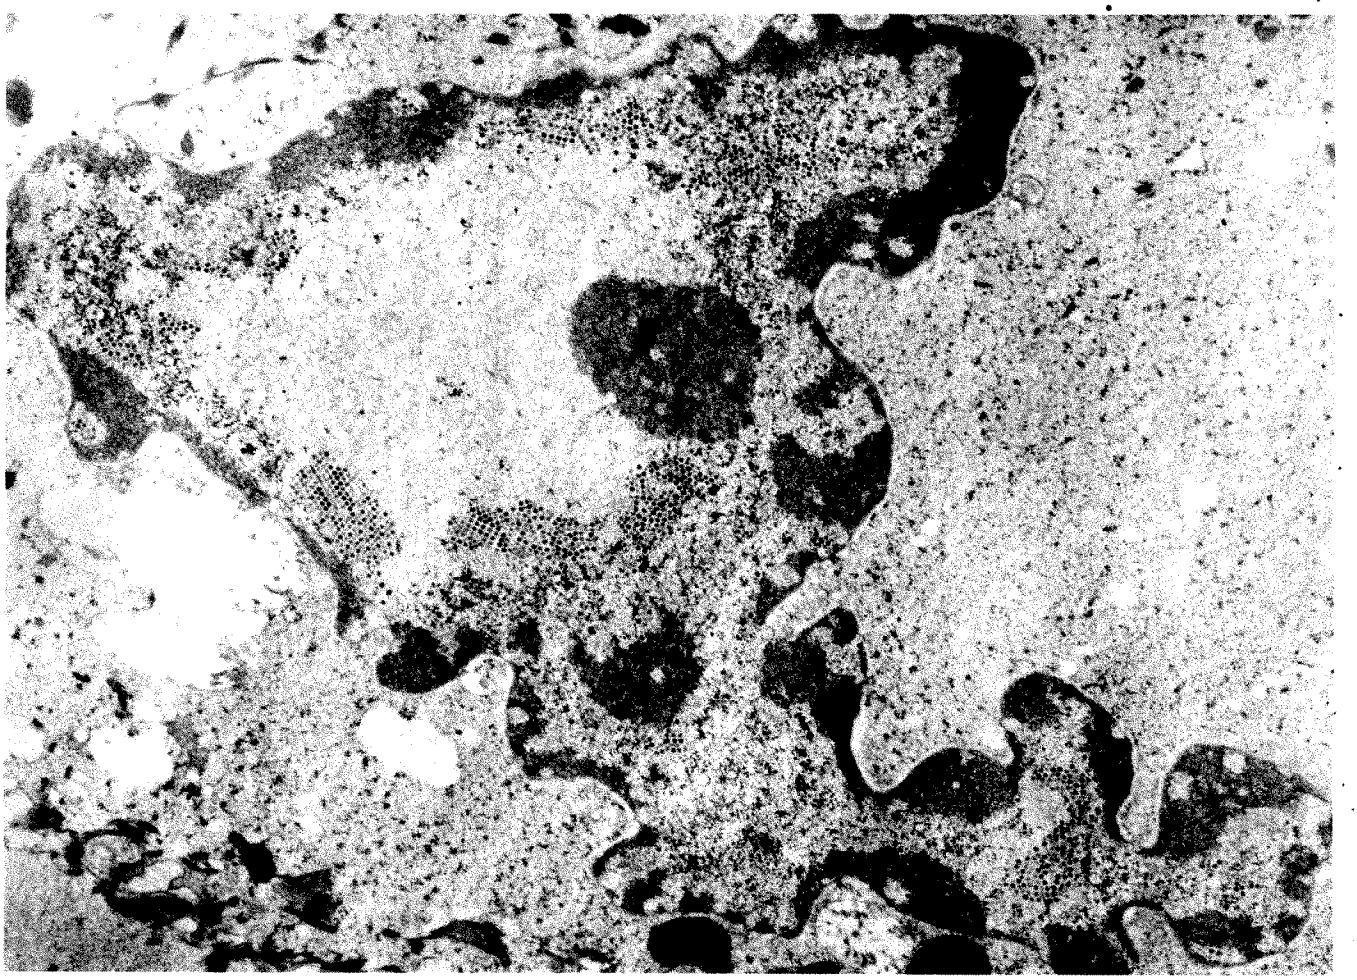

Fig 4.—Electron micrography showing crystalline arrangement of papovavirus virions within nucleus of keratinocyte at level of stratum granulosum (original magnification ×17,200).

aliquot of plasma was removed for determination of immunoglobulin levels by radial immunodiffusion. Lymphocytes were purified on Ficoll-Hypaque density gradients.[3] The T-lymphocyte populations were identified by a sheep red blood cell (SRBC) rosette assay.[4] Unsensitized SRBCs were incubated with lymphocytes for five minutes at 37 C, centrifuged at 200xg for three minutes, and further incubated at 4 C for one hour. The pellet was gently resuspended and the cells examined in a hemocytometer. Cells binding three or more SRBCs were counted as T-lymphocytes. An erythrocyte antibody complement (EAC) rosette assay was used to quantitate numbers of B-lymphocytes.[6] The SRBCs were incubated with antibody (E hemolysin) and complement (B10 D2 mouse serum) before mixing with the lymphocytes. The B-cell rosettes were counted as in the T-lymphocyte assay.

The response of purified lymphocytes to multiple dilutions of mitogens, a crude preparation of phytohemagglutinin (PHA-M), a highly purified PHA-HA17, and conconavalin-A (CON-A) was determined by incubating triplicate aliquots of 10^5 lymphocytes in plastic culture plates at 37 C in a humidified atmosphere with 5% CO_2. After 67 hours, 50 μl of tritiated thymidine (1 μCi/ml) was added. The plates were incubated an additional 24 hours, harvested, and assayed for radioactivity. Response to multiple concentrations of streptokinase-streptodornase (SK/SD) was assayed as previously described.[7] Three normal control individuals were studied simultaneously with the patients. The stimulating and responding potential of the patients' lymphocytes was determined in mixed lymphocyte cultures (MLC).[8] Unidirectional reactivity was achieved by prior treatment of stimulator cells with mitomycin.

The patients were skin tested to a variety of antigens. Intracutaneous tests were performed using *Candida* antigen, purified protein derivative–intermediate strength, histoplasmi, coccidiodin, trichophytin, and SK/SD. Epicutaneous tests to 34 common contact allergens employed a standardized screening try. Skin tests were read at 48 hours.

RESULTS

All histologic specimens examined by light microscopy were essentially identical in appearance. The stratum corneum was thickened in a basket-weave pattern. There were focal areas of thickened stratum granulosum containing enlarged cells with glassy, pale-staining cytoplasm and large empty nuclei. Clusters of these cells extend deep into the stratum malphigium (Fig 3, left). The epidermis was only slightly thickened, and the basal cell layer was not altered.

Specimens obtained from surgery performed on patient 1 in March 1975, were reviewed. The lesion removed from the left wrist showed moderate

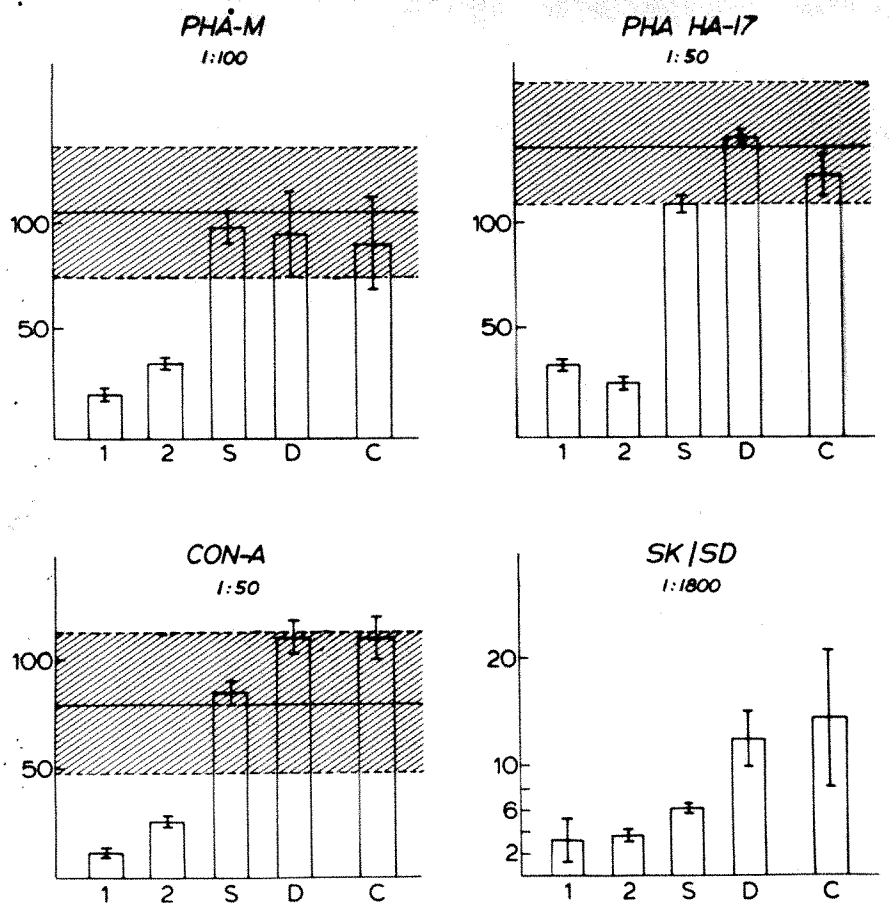

Fig 5.—In vitro responses to mitogens and SK/SD. Bar graphs represent tritium uptake of triplicate cultures for each patient (1 and 2), a sister (S), the daughter of patient 1 (D), and nine cultures from three normal controls (C). Data expressed as counts per minute × 10^{-3} with one standard deviation. Shaded area plots the mean and standard deviation of 300 normal individuals tested in same laboratory.

dysplastic changes; the epidermis was thickened, and the cells of the stratum malphigium were in a disorganized pattern. The underlying dermis contained a chronic inflammatory infiltrate. A lesion removed from the right second finger was a squamous cell carcinoma in situ; the epidermis was thickened and irregular, and the squamous cells were pleomorphic with basophilic cytoplasm and multiple large nuclei with prominent nucleoli. Individual cell keratinization and mitoses were noted. The basal cell layer was intact, and the dermis contained an inflammatory infiltrate with plasma cells and lymphocytes (Fig 3, right). Epidermal keratinocytes in the region of the stratum granulosum contained virions packed in a crystalline arrangement at the periphery of the nuclei. Virions displayed the capsid structure characteristic of papova viruses (Fig 4).

The patients had normal levels of plasma immunoglobulins. Values for case 1 in units of milligrams per 100 ml were as follows: IgA, 280; IgG, 1,700; IgM, 58; and IgE, 131. The corresponding values for case 2 were 468, 1,770, 58, and 418 mg/100 ml. Both patients had normal percentages of T-lymphocytes and B-lymphocytes as determined by the rosette assays; case 1 had 70% to 78% T-rosettes and 6% B-rosettes, and case 2 had 64% to 74% T-rosettes and 8.5% B-rosettes. Because WBC counts were normal, these figures also reflected normal absolute numbers of lymphocytes. Stimulation and response in MLC was within the normal range. Optimal blastogenic concentrations of mitogens and antigens were identical in the two patients, one sister, a daughter, and three control individuals. The data in Fig 5 reflect dilutions of PHA-M 1:100, PHA HA-17 1:50, CON-A 1:50, and SK/SD 1:1800. The graphs are expressed as the mean counts per minute (cpm) of triplicate cultures for the patients and relatives and the means of nine cultures from the three control individuals. The means and one standard deviation are plotted against a background of data obtained from the study of 300 normal adults in the same laboratory. These data represent normal mitogen responses through the seventh decade of life.[9] The blastogenic responses to mitogens of the patients' relatives and the three normal individuals run simultaneously as reagent controls agree with the normal laboratory values of the assays, but both patients are markedly depressed with 20% to 25% of normal function. Statistical analysis of each mean mitogen response results in a value of $P < .01$. Response to SK/SD antigens cannot be compared in the same fashion to a control population, because the response is under genetic control.[7] However, the patients show a much lower response to SK/SD than their relatives or the reagent controls. All intracutaneous and epicutaneous tests performed on the patients were negative. The only cutaneous reaction was that of patient 1, who develped 0.5 cm of erythema and induration to trichophyton.

COMMENT

Epidermodysplasia verruciformis was first described by Lewandowsky and Lutz in 1922.[10] Although the disease is very rare, in recent years several groups of investigators have been able to study small numbers of patients. The results of these investigators include the electron microscopic demonstration of virions by Ruiter and van Mullen,[2] autoinoculation and heteroinoculation experiments by Jablonska and Formas,[11] and the study of thymidine and uridine incorporation in the warty and carcinomatous lesions.[12,13] Several investigators have been intrigued by the presence of virions in wart-like lesions and precancerous keratoses but not in the carcinomas.[14,15] These reports have not explored the role of immunity in the pathogenesis of EV.

We report two siblings with EV. The appearance of many of their skin lesions was identical to that of large, flat warts or common warts, but both patients had flatter, more pigmented lesions with adherent and wrinkled scales. The latter lesions seem particularly characteristic of EV. The histologic appearance of the wart-like and flatter lesions was identical. Like warts, the pathologic changes appeared in foci at the stratum granulosum, but rather than profound vacuolation, the involved cells were enlarged with glassy cytoplasm and empty nuclei. The involvement extended deep into the stratum malphigium. These subtle clinical and histologic differences seem to place EV apart from patients with extensive, disseminated warts. Also, the recorded familial association and the appearance of carcinomas in patient 1 support the diagnosis of EV.

The wart-like lesions were packed with a crystalline array of papovavirus virions at the periphery of nuclei within the stratum granulosum. The malignant lesions were not available for electron microscopic study, so we could not show that the carcinomas arose from wart-like lesions. However, other investigators have observed virions in premalignant lesions,[14] and this supports the concept of viral carcinogenesis in EV. The clinical association of warts leading to carcinoma is similar to that of rabbits, where Shope papilloma virus is oncogenic in nonregressor rabbits.[16] The EV patient in a sense is a nonregressor human.

We have measured depressed mitogen and antigen responses in both patients. The patients had normal numbers of T-lymphocytes and B-lymphocytes and normal serum immunoglobulin levels. Mixed lymphocyte cultures measure function of a small subset of lymphocytes, and this function appeared intact. However, neither patient's lymphocytes reacted adequately to plant mitogens or SK/SD antigens, and the patients had cutaneous anergy to a variety of test antigens.

Depressed immune function in these patients with EV may indicate an inherited defect in an immune response gene. This defect must differ from patients with primary immunodeficiency states, who in addition, have lower numbers of T-lymphocytes and an increased susceptibility to a variety of viral and fungal diseases. The EV patients had the childhood viral diseases without complications. Could then the alteration of immune function have resulted from an extensive viral infection? Depressed T-lymphocyte function occurs transiently following infection with certain viruses,[17] and may accompany chronic diseases, eg, sarcoid or lymphoma. If the depressed immune function resulted from viral infection, it cannot account for the infection but could explain the susceptibility to viral carcinogenesis. In this situation, the EV patients would be analogous to patients treated with immunosuppressive therapy, who are at increased risk in regard to tumor formation. The questions raised by our observations cannot be answered from studies of these patients alone. It will be necessary to compare additional cases of EV and follow the immune factors of uninvolved family members.

A final consideration is the identity of the virus involved in EV and its relationship to the immunologically compromised host. Yabe and Sadakane[18] presented evidence for the presence of human papilloma virus (HPV) in EV lesions using antisera prepared to HPV. Virions isolated from EV lesions were not examined or used for antisera. The recent descriptions of small human papovaviruses isolated from immunosuppressed patients[19] and the oncogenic potential of the small viruses,[20] emphasize that more than one human papovavirus does exist, and more direct identification of EV virus is necessary. We have successfully isolated virions from case 1 and plan further experiments to identify the virus involved.

This investigation was supported by Public Health Service grant CA15955 and contract CB43853 from the National Cancer Institute, and training grant T01-AM05560.

Eruptive Vellus Hair Cysts

Nancy B. Esterly, MD; David F. Fretzin, MD; Hermann Pinkus, MD

• **Two children had a hyperpigmented monomorphous papular eruption of several years' duration. Biopsy specimens demonstrated cysts in the middle dermis that contained multiple fragmented vellus hair shafts. The eruption in one child involuted spontaneously. The cause of these lesions is obscure. The term eruptive vellus hair cysts is proposed for this entity.**

(*Arch Dermatol* 113:500-503, 1977)

Noninfectious, asymptomatic, and persistent papular eruptions are relatively uncommon in young children. The differential diagnosis includes diseases characterized by perforating lesions, as well as nevi and hamartomas involving adnexal structures. Histologic studies are often required for definitive diagnosis of these disorders. A few chronic papular eruptions that do occur with reasonable frequency in the pediatric age group, such as milia, keratosis pilaris, and granuloma annulare, are usually recognizable by their clinical morphology alone.

We recently encountered two children with a papular eruption that was atypical in clinical appearance and distribution for the common cutaneous disorders. On histologic examination, these lesions were found to be an unusual cystic alteration of the hair follicle.

REPORT OF CASES

CASE 1.—A 6-year-old girl was seen in the Pediatric Dermatology Clinic in May 1974, because of a papular eruption of approximately two years' duration. The lesions were first noted on the chest in the parasternal areas. Subsequently, additional lesions developed on the flexor surface of both forearms and in the popliteal fossa bilaterally. The papules were persistent, but asymptomatic, and never became infected or crusted. There was no evidence of antecedent trauma to the involved skin and, other than occasional applications of an emollient, (Lubriderm) no skin preparations were used. The family history was negative for skin disorders.

Her past medical history was of note in that she had numerous episodes of upper respiratory infection, tonsillitis, and otitis media, as well as two episodes of pneumonia during the first few years of life. At age 3 years, cardiomegaly was discovered on a routine chest film obtained for a preschool medical examination, and on the basis of abnormal ECG findings, a diagnosis of resolving viral myocarditis was made. During the past two years, she has enjoyed good health and attended school regularly.

Physical examination at the time of presentation was normal except for the cutaneous findings. Scattered over the flexor surface of the forearms were 30 to 50 discrete, red-brown, 1 to 2 mm, soft, smooth papules, only one of which had a hyperkeratotic crust (Fig 1 and 2). Similar lesions, numbering about 20, were grouped in each popliteal fossa. Another 30 or so less sharply demarcated 1 mm lesions were seen on the anterior chest wall. Two biopsies were obtained, one from the flexor surface of the forearm and another from the popliteal fossa (see below).

There was no resolution following application of various keratolytic agents and acne preparations. Peeling by daily use of salicylic acid in a propylene glycol gel (Keralyt) under occlusive wraps resulted in decreased prominence of the lesions, but was not felt to be of lasting benefit. During the first year of observation, none of the lesions regressed spontaneously, and occasionally new papules developed in involved areas. Suddenly, approximately 14 months after the first visit, the papules regressed spontaneously and disappeared completely on the chest and legs. When examined in August 1975, only a few papules were evident on the forearms.

Histopathological Findings.—Multiple hematoxylin-eosin sections were reviewed from two papules that revealed similar histopathologic findings. The overlying epidermis appeared minimally acanthotic. In the midcorium, there was a small cystic structure lined by squamous epithelium 3 to 7 cell layers thick that contained laminated keratinous material and vellus hairs presenting as multiple transverse or oblique sections. In some areas there was maturation of the squamous cells with the production of keratohyaline granules. In several adjacent sections, a ventral bulge composed of more basaloid cells extended from the cyst wall. However, serial sections in this area failed to demonstrate progres-

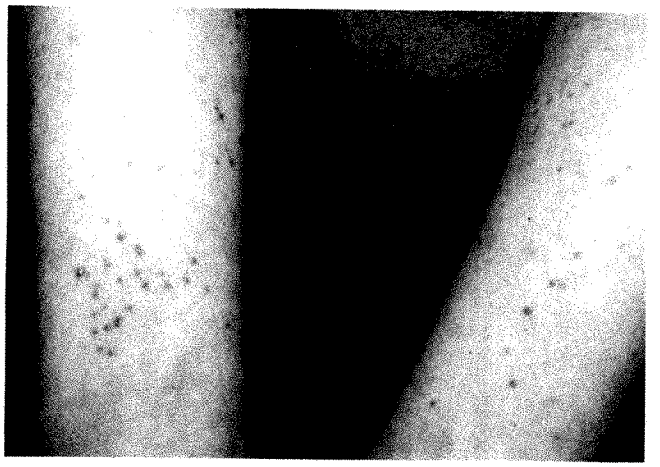

Fig 1.—Multiple hyperpigmented papules on flexor surface of forearms of patient 1.

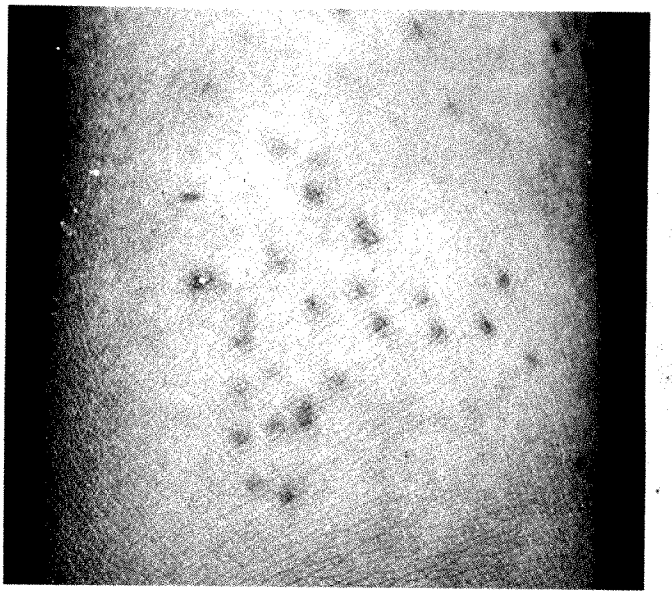

Fig 2.—Papules on forearm of patient 1. Normal markings are retained on overlying skin.

sion to a hair bulb, nor was an attachment to the overlying epidermis seen in either of the two specimens. A modest fibrous sheath, numerous supporting capillaries, and a sparse perivascular lymphocytic inflammatory cell reaction surrounded the keratin cyst (Fig 3 and 4).

Case 2.—A 7-year-old boy was referred to the Pediatric Dermatology Clinic in April 1975, because of a papular eruption on the anterior chest that had been present for approximately three years. It was first noticed by his mother during the summer months when he usually did not wear a shirt. The papules were asymptomatic and never became infected or hyperkeratotic. They gradually darkened during subsequent months, but it was unclear whether new lesions had continued to appear.

The patient was said to be in excellent health; he took no medications and used nothing but ordinary toilet soaps on his skin. The family history was negative for skin diseases.

Physical examination was completely normal except for the skin. There was a 3 cm, cafe au lait spot on the left-upper arm and another smaller lesion on the anterior chest. Over the central portion of the anterior thorax was an eruption consisting of about 50 dark brown, noninflammatory, 1 to 2 mm papules (Fig 5). Two of the papules were removed by punch biopsy for histologic examination. No therapy was instituted.

Histopathological Findings.—Serial hematoxylin-eosin sections were examined from each of two small papules removed from the anterior chest wall. Both specimens showed a small keratin-filled cyst in the middle dermis containing numerous transversely or obliquely cut portions of vellus hair. One cyst had a telogen hair bulb extending from the lower surface towards the subcutis.

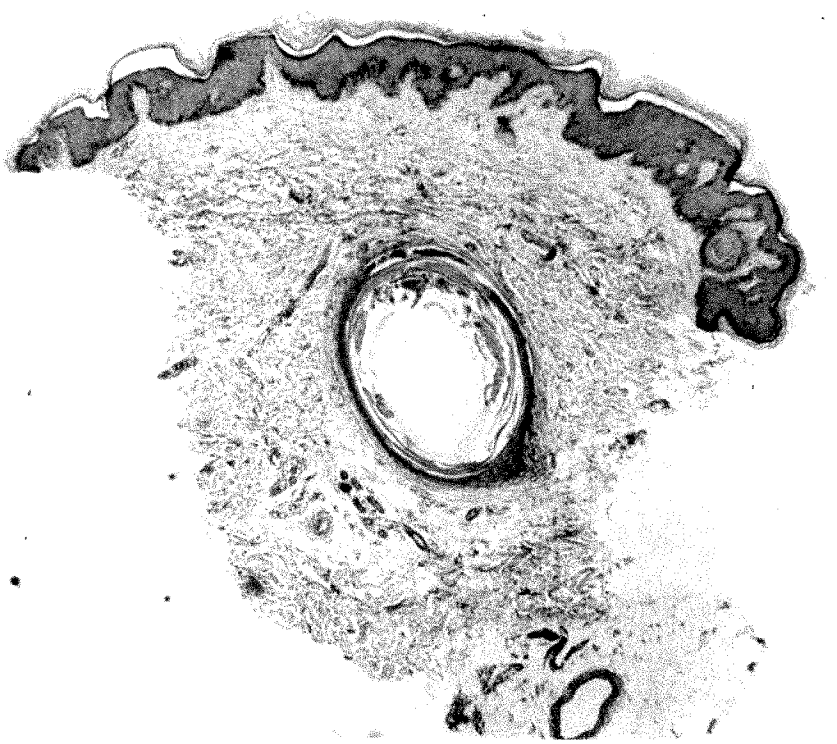

Fig 3.—Hair cyst in midcorium containing laminated keratinous material (hematoxylin-eosin, original magnification ×75).

There was also an epithelial invagination from the surface epidermis toward the hair cyst, although no definite connection was found in serial sections of this area. The cyst walls were composed of 5 to 12 layers of keratinizing epithelium with focal areas of a granular layer noted. A modest lymphocytic inflammatory reaction surrounded several small vessels adjacent to the cyst wall. The cyst was enclosed in a loose fibrous sheath (Fig 6).

COMMENT

The two children described in this report had a distinctive focal papular eruption that seemed unlike any

previously known disease. Despite the banal and asymptomatic nature of the lesions, the unusual distribution and monomorphous quality of the eruption in the first child prompted us to seek a histologic diagnosis. A pediatric resident who had seen this patient in the clinic then referred the second patient because of the striking similarity in the appearance of the lesions.

Although all of the perforating disorders might be considered in the differential diagnosis, vellus hair cysts differ clinically from other entities in many respects. They lack the central umbilication and keratotic plugs characteristic of perforating collagenosis.[1-5] In addition, since the lesions of perforating collagenosis are induced by trauma, a Koebner response can usually be identified, and sites of predilection are the dorsum of the hands, the forearms, and the knees. The lesions of perforating collagenosis disappear spontaneously after a course of a few weeks, and lesions in all stages of development usually can be identified. Perforating folliculitis[6] might be considered as well, however, these erythematous follicular papules predominate on the extremities and also contain a visible central keratotic plug. Kyrle disease,[7-8] rare in young children, consists of large follicular and parafollicular papules that aggregate to form plaques in involved areas. Elastosis perforans serpiginosa[9] is an eruption of annular, ovoid, or serpiginous configuration, often occurring in isolated anatomic sites. Milia are discrete and pearly in appearance and have a predilection for the face and sites of trauma.

The absence of inflammation made a diagnosis of bacterial folliculitis unlikely. The sites of involvement and clinical appearance of the lesions were incompatible with a diagnosis of keratosis pilaris. Although appendageal malformations were also considered, the lesions in these children did not resemble any known adnexal tumors.

The histological description of epithelial cysts of the skin can be readily found in standard dermatopathology textbooks. The distinguishing patho-

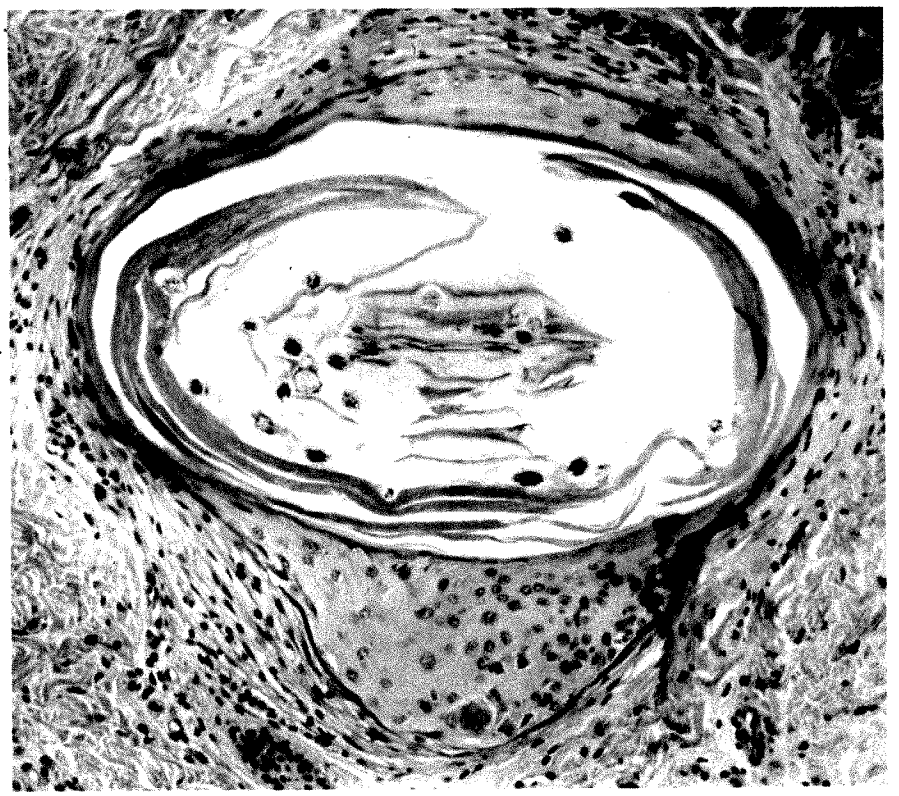

Fig 4.—Keratinous hair cyst lined by squamous epithelium and showing cut portions of hair shaft. Ventral bulge suggests follicle remnant (hematoxylin-eosin, original magnification ×375).

Fig 5.—Numerous hyperpigmented papules on anterior thorax of patient 2.

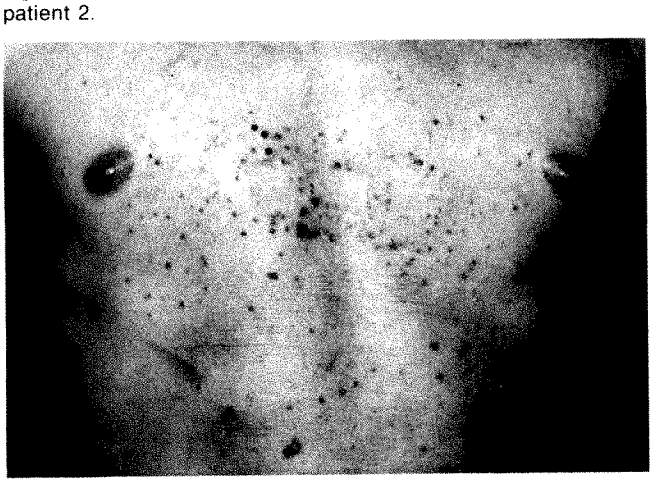

Fig 6.—Keratinous hair cyst in midcorium containing vellus hair cut transversely or obliquely in numerous places. Telogen hair follicle projects from its base (hematoxylin-eosin, original magnification ×100).

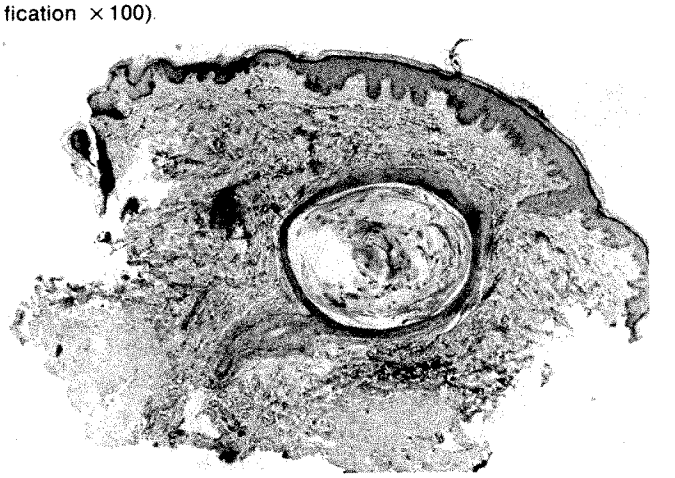

logical changes in our two patients appear to be the size and location of the cysts in the middle and deep dermis and the inclusion of vellus hair shafts (trichostasis). The presence of a true telogen hair bulb or an epithelial bulge extending from the proximal edge of the cyst in serially sectioned specimens identifies the lesion as arising in a true hair follicle. A definite attachment, however, to the superficial portion of a pilar complex could not be clearly substantiated. One may speculate that the pathogenetic development of the cyst is initiated by the loss of epidermal contact allowing for retention of keratinous material and hair shafts. Secondary hair bulb atrophy may be a consequence of this process.

Except for the uncommon dermoid cysts and steatocystoma multiplex, most of the ordinary keratinous cysts do not contain hairs. Additionally, the absence of sebaceous glands or other adnexal structures associated with the cyst wall in our patients clearly differentiated these lesions from the former variety of cysts. The possibility of the cysts being young dermoid cysts prior to the hyperplasia of sebaceous or adnexal structures is not likely, especially in view of their disappearance in one patient. The clinical and histological features readily allow differentiation from milia.

A reference from the early German literature[10] suggested the term "rollhaarcyst" for cystic lesions containing coiled hairs. However, the authors describe an acquired lesion in adults, probably due to traumatic obstruction of the follicle of a terminal hair on the abdomen.

The exact etiology of eruptive vellus hair cysts is obscure. We were unable to elicit a history of trauma, friction or occlusion of affected areas in either patient. The establishment of a hamartomatous origin for vellus hair cysts is difficult since clinical data indicate that the lesions are not present at birth or in infancy and because of their spontaneous involution in one of the two children.

Since this manuscript was submitted, two additional children have been seen with eruptive vellus hair cysts. The lesions of both were so characteristic that the correct diagnosis was made prior to biopsy. The first child, a 4-year-old girl, noted her lesions one week prior to the clinic visit. Date of onset was unknown in the second child, a 9-year-old boy, who was brought in by a new foster parent for routine physical examination. Papules were distributed on the flexor surfaces of the wrists, medial surfaces of the upper arms and thighs, popliteal fossae, and anterior chest.

The histopathological findings of a lesion from one of these patients was similar to our original cases. However, serial sections of a lesion from the second patient revealed several unique features (H.P.). There was a mid-dermal cyst with two separate pilar muscle attachments laterally and two rudimentary hair roots. Within the cyst were one or more rolled-up vellus hair shafts. At the upper pole, the cyst was connected to the surface epidermis. A keratotic plug devoid of hair occupied the follicular infundibulum. The following possible pathogenetic mechanisms can be suggested to explain the above findings: (1) a keratinous plug at the follicular infundibulum deflected the hair to the deeper part of the follicle causing cystic dilatation; (2) at least in one instance, two hair roots of a compound follicle united below the surface and had a common infundibulum; (3) there is gradual disruption of the connection between the proximal and distal follicle; and (4) an initially abnormal hair follicle is predisposed to these cystic changes.

Irene Goldberger provided technical assistance.

Laser Treatment of Extensive Mixed Cavernous and Port-Wine Stains

Leon Goldman, MD, Ronald Dreffer

• **An extensive, disfiguring, mixed nodular cavernous and port-wine stain of the face of an adult who had psoriasis and diabetes was treated with ruby and argon lasers for a period of seven years with substantial cosmetic improvement. There was no deep scarring, secondary granuloma telangiectatic reactions, or chronic radiation changes. Prolonged treatments were necessary because of the small size of the laser emission impact areas.**

(*Arch Dermatol* 113:504-505, 1977)

The port-wine stain has continued to offer a therapeutic challenge because of its intractable nature. The vascular component of the port-wine stain is an adult type of blood vessel and not the blastoma found in the cavernous type of angioma. The port-wine stain never disappears or rarely ever fades spontaneously. It is not responsive to x-ray radiation. Tattooing with pigments such as titanium dioxide or zinc oxide often gives a mottled grayish appearance. Port-wine stains in the eyelid cannot be tattooed. In the older adult, the port-wine stain may become pendulous as connective tissue changes develop. At

Fig 2.—After repeated ruby and argon laser treatments for seven years.

this stage, plastic surgery may be of use.

In the mixed type of port-wine stain are superficial areas of the small port-wine-fixed capillary-type vessels plus deeper areas of large cavernous vessels. Unlike the primary cavernous angioma, this cavernous component does not subside spontaneously. The consequent nodular appearance does not lend itself well to covering preparations.

For more than 13 years port-wine stains have been treated with investigative laser surgery at the Laser Laboratory of the University of Cincinnati Medical Center. The laser was used because laser emissions in the range of visible light show greater absorption in pigmented masses. This includes melanin, so-called melanoid, hemoglobin, and oxyhemoglobin pigments. The ruby laser emissions of 694.3 nm are absorbed more in black pigment but with high enough energy densities, 70 to 90 joules/sq cm, these emissions are absorbed more in red than in white areas. In energy densities of 20 to 40 joules/sq cm there is but little absorption in red areas. As we indicate subsequently, the emissions of the argon laser are absorbed more in hemoglobin. Treatment with the pulsed ruby laser produces small 2.1-sq cm circular whitened areas in port-wine stains. The Q-switched ruby laser, nanosecond-pulsed, is not effective in the treatment of port-wine lesions, most likely because its emissions with such short pulses are mostly reflected by the red color of the stain.

Our early investigative studies have shown that the argon laser emission spectra, 488.0 to 514.5 nm, is effective in the treatment of port-wine stains. Its emissions are similar to the absorption spectra of hemoglobin. Often the narrow beam diameter makes this instrument impractical for the treatment of large areas, in spite of repetitive treatments. However, commercial models for the argon laser treatment of port-wine stains are available for dermatologic therapy. Also, the Nd-YAG laser is now being used experimentally in the same manner as the argon laser. Another type of irradiation under investigative study is high-output incoherent infrared.

The following case is reported to show the effect of the laser treatment for an extensive disfiguring mixed port-wine mark.

REPORT OF A CASE

A 54-year-old man had had this lesion ever since birth, with the nodularity of the surface becoming more marked in recent years. Electrocoagulation and cryosurgery had been tried without benefit. Examination showed an intense reddened nodular lesion occupying the entire right half of the forehead, extending into the scalp and involving the eyelid. There was no intraocular involvement (Fig 1).

For a period of seven years, repeated ruby laser treatments were given at intervals of three to four weeks to the entire area. The treatments were not painful and were given without anesthesia. Usually five to six impacts were given at each session. The energy density of each impact of the pulsed ruby laser was 55 to 75 joules/sq cm, 2.1-sq cm area, 2.0-m sec pulses. Argon laser treatments were given with power densities of 1 to 3 watts with beam diameter 1.5 to 3.5 mm. With special eye protection,[1-3] only the upper portion of the eyelids were treated.

The tissue reaction of the ruby laser was a coagulation necrosis of a circular area approximately 1.6 cm in diameter. This required about three weeks to heal.

Argon laser treatments were started Jan 23, 1975, repeated every other month, and have continued to the present, 20 to 30 impacts given at each session. These were small areas, 1.5 to 4.0 mm, 1.5 to 4.0 watts, 0.5 to 1.0 m sec.

RESULTS

After laser treatments, flattened areas of decreased color developed. It is evident that even with the current primitive instrumentation there has been significant improvement in this patient. The obvious difficulty is the small target areas produced and the need for higher output instrumentation with increased energy and power densities to provide for treatment of larger areas. With adequate protection there was no hazard to the eyes of the patient. To date, there has been no evidence of any recurrence in any area treated, even those areas affected seven years ago.

At present, the patient has flattened, reddened areas with occasional irregular whitish areas (Fig 2).

The port-wine mark on the eyelids can be treated if the patient desires. This can be done with the use of protective shields in the eyes, while the patient is under tetracaine hydrochloride (Pantocaine) anesthesia.[1-3]

Persa-Gel™

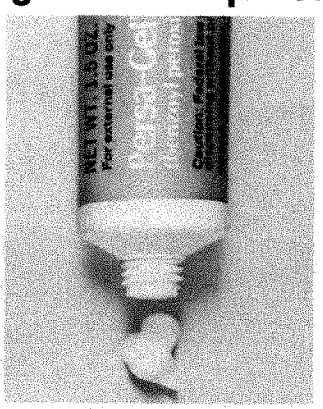
(BENZOYL PEROXIDE)

Unique Acetone Gel 5% and 10%

TEXAS PHARMACAL COMPANY
San Antonio, Texas 78296

Unique acetone base enhances stability and cosmetic acceptability.

Two and one-half year dating
No refrigeration required



CAUTION: Federal law prohibits dispensing without prescription.
DESCRIPTION: Persa-Gel™ 5% contains 5% benzoyl peroxide; Persa-Gel™ 10% contains 10% benzoyl peroxide; in a gel base containing acetone, carboxyvinyl polymer, triethanolamine, sodium lauryl sulfate, propylene glycol and purified water.
ACTIONS: Benzoyl peroxide is primarily effective because of its drying, peeling and antiseptic action.
INDICATION: For adjunctive topical therapy of acne vulgaris.
CONTRAINDICATIONS: Benzoyl peroxide is contraindicated in patients with acute inflammation and in patients with a history of hypersensitivity to any of the components of the preparation.
PRECAUTIONS: If excessive irritation develops, discontinue use and institute appropriate therapy. After the reaction clears, treatment may often be resumed with less frequent applications. Avoid contact with eyes, eyelids, lips and other mucous membranes, and anterior neck. May bleach hair and colored fabrics.
ADVERSE REACTIONS: Allergic contact dermatitis and severe erythema with crusting have been reported with topical benzoyl peroxide.
DOSAGE AND ADMINISTRATION: Persa-Gel™ (benzoyl peroxide) should be applied thinly to cover affected area after cleansing with non-medicated soap and water or a degreaser. Initial application once daily before bedtime is recommended, increasing to twice daily as tolerance develops. Feelings of warmth and stinging and slight erythema may be noted initially. It is advisable to initiate therapy with Persa-Gel™ 5% shifting to the use of Persa-Gel™ 10% after 3 or 4 weeks, or earlier if tolerance to the 5% has been determined. Therapeutic results are usually seen within 2 weeks with continued improvement therafter.
HOW SUPPLIED: Persa-Gel™ 5% 1.5 oz. tubes
(NDC0064-8610-31)
Persa-Gel™ 10% 1.5 oz. tubes
(NDC0064-8600-31)

New From Dermik

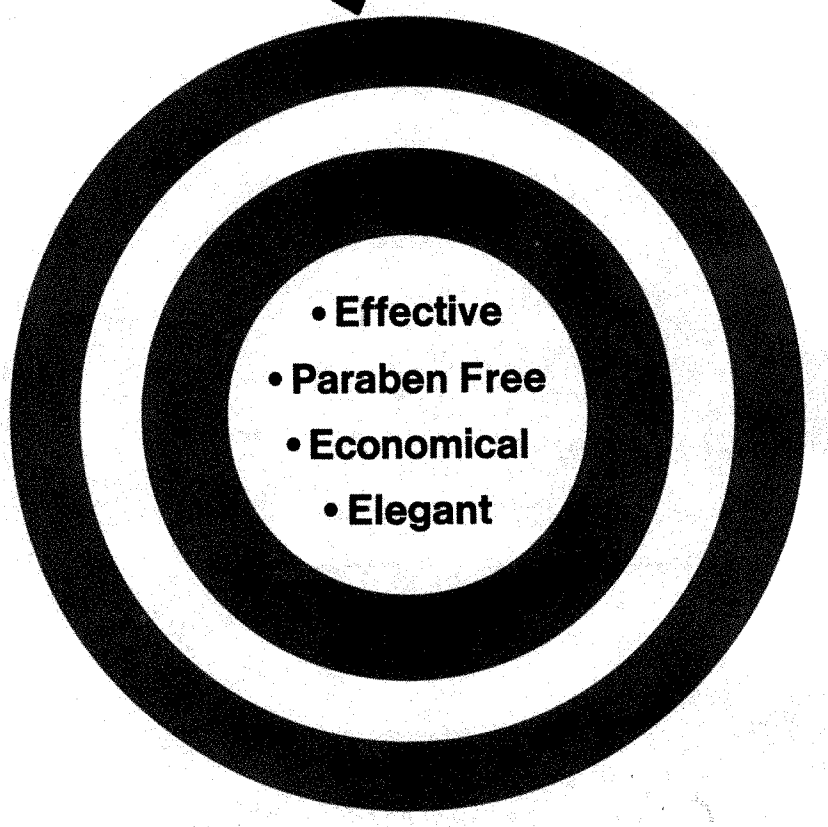
Hytone®

CREAM (HYDROCORTISONE)

2½%

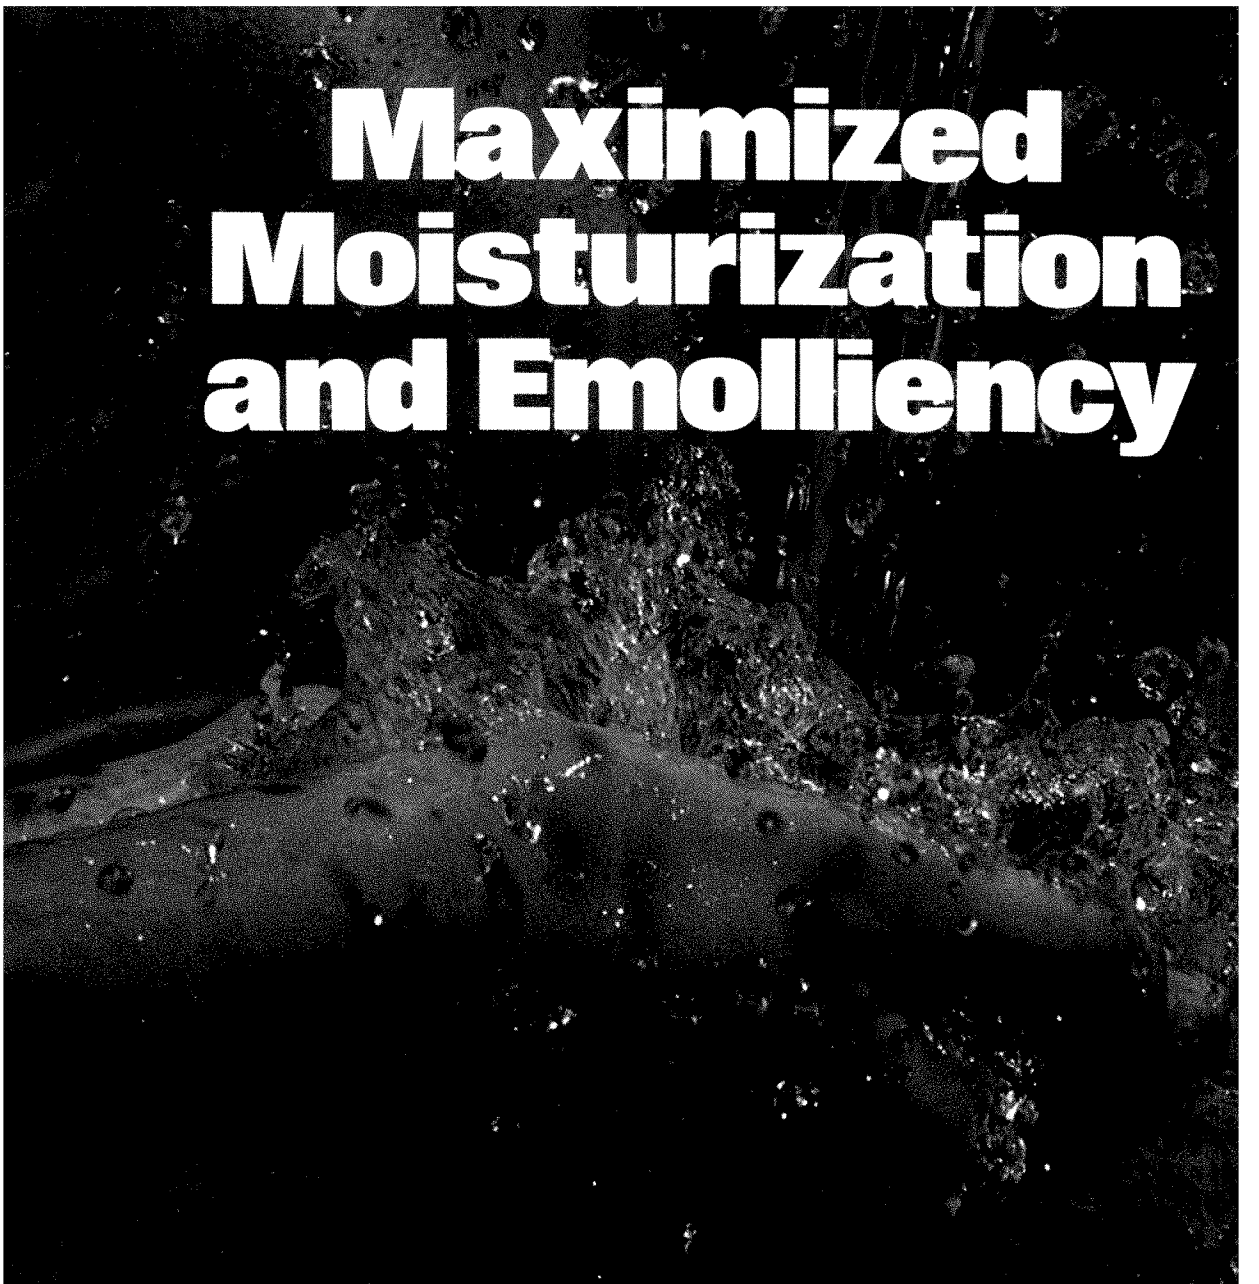
hydrocortisone safety . . . new high potency . . .

- Atopic Dermatitis
- Severe Diaper Dermatitis
- Seborrheic Dermatitis
- Lichen Simplex Chronicus
- Pruritus Ani



Dermik Laboratories, Inc., Fort Washington, Pa. 19034
WHERE RESEARCH AND ECONOMY COME FIRST!

DESCRIPTION – Hydrocortisone 2½%, 1% and ½% in a water-washable cream containing purified water, propylene glycol, isopropyl myristate, cholesterol and related sterols, cetyl alcohol, sorbic acid, glyceryl monostearate, polysorbate 60, sorbitan monostearate and polyoxyl 40 stearate.
ACTIONS – Topical corticosteroids are effective primarily because of their antiinflammatory, antipruritic, and vasoconstrictive actions.
INDICATIONS – For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.
CONTRAINDICATIONS: In viral diseases of the skin such as varicella and vaccinia and in patients with a history of hypersensitivity to any component. Not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.
WARNING: Should not be used extensively, in large amounts, or for prolonged periods in pregnancy.
PRECAUTIONS – If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.
ADVERSE REACTIONS – The following local adverse reactions have been reported with topical corticosteroids, either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.
DOSAGE AND ADMINISTRATION – Apply to affected areas 3 or 4 times daily.
HOW SUPPLIED: Tubes – ½ oz., 1 oz.
CAUTION – Federal law prohibits dispensing without prescription.



Maximized Moisturization and Emolliency

A natural humectant which occurs in normal healthy skin:

Sodium pyrrolidone carboxylate (NaPCA):
Proven superior to the most commonly-used humectants in water-holding capability and restoration of extensibility.[1] NaPCA is extremely hygroscopic, imbibing 60% of its weight in water at a humidity of 58%.[2]

A superior humectant which *locks* moisture into the stratum corneum:

Lactic Acid:
Lactic acid has the unique ability to be adsorbed onto the cells of the stratum corneum and to be retained there even after rinsing with water for 30 minutes, long after "the effect of other humectants was lost."[1]

An occlusive lipid barrier to h retard evaporation:

Special emulsion base is highly conce trated and helps reduce water loss fr the stratum corneum.

Formula: Lactic Acid USP 5.0%
Na-PCA 2.5%
in an oil-in-water lotion base containing: purified water mineral oil, isopropyl palmitate, coceth-6, sodium hy glyceryl stearate, myristyl lactate, cetyl alcohol, carbor imidazolidinyl urea, fragrance, dehydroacetic acid.

new LactiCa

A genuine breakthro in the management of dry skin.

More physiologic: LactiCare's unique formula restores humectants which occur naturally in normal healthy skin.

Prolonged protection that won't easily wash away: Unlike most humectants which easily may be rinsed away, lactic acid is adsorbed onto the cells of the stratum corneum and remains there to improve their water-retention ability, even after extended immersion in water.

Better moisture-binding ability: Both of the major humectants in LactiCare have been shown superior to the most commonly-used hygroscopic agents in their ability to absorb moisture and supply it to the stra corneum.[1]

Greater economy: LactiCare is a h centrated lotion with a pleasant, t consistency. It should be used sp less often than ordinary lotions. over body use costs only pennie

Formula: Lactic Acid USP 5.0%
Na-PCA 2.5%
in an oil-in-water lotion base containing: purifi mineral oil, isopropyl palmitate, coceth-6, so glyceryl stearate, myristyl lactate, cetyl alcoho imidazolidinyl urea, fragrance, dehydroacetic

THE LOS ANGELES DERMATOLOGICAL SOCIETY
March 12, 1975

Marian M. Brubaker, MD, Recorder

Porphyria Cutanea Tarda With Sclerodermoid Changes. Presented by PERRY SCHOLNICK, MD, NORMAN BROOKS, MD.

A 61-year-old man with a four-year history of tightening of the skin of the chest, neck, scalp, and arms has had occasional bullous lesions and fragility of the skin on the dorsa of the hands. There was no history of photosensitivity, except for mild burning of the eyes on exposure to sunlight. He had been a heavy consumer of alcohol for ten years, but not for the past three years. The important findings were hidebound skin on the anterior portion of the chest, neck, and scalp, with erosions on the dorsa of the hands. Conjunctival infection was present.

Laboratory studies showed elevated levels of uroporphyrins (2,090 μg/24 hr; normal, <57 μg/24 hr) and coproporphyrins (348 μg/24 hr; normal, <234 μg/24 hr). The hematocrit reading was 42%, the serum iron value was 113 μg/100 ml (normal, 65 to 175 μg/100 ml), and the serum iron-binding capacity was 298 μg/100 ml (normal, 250 to 400 μg/100 ml). The results of liver function tests were normal, except for a slightly elevated SGPT level. Hepatomegaly was noted on a liver-spleen scan.

The skin biopsy specimen showed thickening of the dermis, with loss of distinction between papillary and reticular layers and focal infiltration by chronic inflammatory cells. The pathologic diagnosis was consistent with morphea.

Discussion

DR LEO INDIANER: Histologically, the epidermis is relatively normal and has binding of the sweat coils with loss of the subcutaneous fat around the sweat coils. There is replacement of the subcutaneous fat by light-staining collagen. One point that has never been made in the literature distinguishing ordinary scleroderma from scleroderma of porphyria is the looser weave of the collagen in sclerodermoid porphyria.[1] In the upper area of the dermis, there are dilated lymphatics and a mild inflammatory infiltrate with edema and basophilic amorphous material that represents hyaluronic acid deposits. This is reported in small quantities in scleroderma as well.[2] The lower area of the dermis, adjacent to subcutaneous fat, has a blood vessel with eosinophilic fibrillar material in its wall. So we see a scleroderma-like picture, with a lighter weave of the bundles, hyaluronic acid, and alterations of the blood vessels. The usual histologic character of porphyria cutanea tarda is that of a subepidermal bullous process with a minimal cellular infiltrate. Often in lesions of erythropoietic protoporphyria, less often in porphyria cutanea tarda, there are deposits of amorphous materials around the blood vessels of glycolipoproteins. Epstein and Tuffanelli,[1] in a study of lesions of porphyria of all types, found not only accumulations of lipids, globulins, and protein polysaccharides, but also tryptophan, sometimes in high degree.

DR WILLIAM REED: Recently, I had a call from Dr Bickers of Columbia University. He said, "You won't believe this, but there's no literature on sclerodermoid porphyria cutanea tarda. There are a lot of case reports, but there is no literature." And, there isn't! There are cases of porphyria cutanea tarda with calcification that have been studied. Authors mention the changes around the blood vessels before various treatments, but no one has done a biopsy after treatment, when the skin becomes soft and almost normal.

DR SCHOLNICK: This is not the only collagen disease in which porphyria cutanea tarda may be present. Early cases of lupus erythematosus were reported in 1955 to 1956 by Irving London in Alabama. He presented several cases of porphyria cutanea tarda that were precipitated in patients receiving chloroquin. Several of these patients were shown to have porphyria cutanea tarda as their only disease.

Why patients get sclerodermoid changes or lupus changes in porphyria cutanea tarda really isn't known, but it is unlikely that it is due solely to the porphyrins. Other porphyrias, in which the porphyrin levels are equally high, do not show sclerodermoid changes or lupus erythematosus. We have taken skin biopsy specimens from this patient, and are going to study his fibroblasts prior to and after treatment to see if there is any identifiable abnormality.

I have no ideas as to what is unique about these particular fibroblasts in presenting a sclerodermoid picture in sun-exposed areas. Biopsy specimens show the classic changes of scleroderma, but if you stain with IgG, you find the changes reported in the blood vessels of porphyria cutanea tarda. The sclerodermoid improves with phlebotomy or other therapy for porphyria cutanea tarda, but why it does is not known. I do not think anyone has any good ideas as to what the relationship between the scleroderma and the porphyria cutanea tarda is.

Ligneous Conjunctivitis. Presented by VICTOR NEWCOMER, MD, ARNOLD KLEIN, MD

A 45-year-old woman developed inflammation of the right eye at the age of two, three weeks after an upper respiratory tract infection, that was diagnosed as diphtheritic or streptococcal conjunctivitis. Enucleation of the right eye was performed, and during the next four to five years, the patient experienced several episodes of inflammation of the right eyelid. At the age of 7, the patient developed a small mass of granulation tissue on the left upper eyelid. This growth was treated by electrocoagulation, silver nitrate application, curettage, 12 grenz-ray treatments, and other modalities, but still the growth continued to recur. She was seen at the University of California at Los Angeles Medical Center at the age of 32, and has been seen subsequently by Dr Victor Newcomer. The lesion of the left eyelid continues to recur, despite multiple excisions. There was no family history of ocular disease. The important finding was a firm, yellow-red, pedunculated lesion of the left conjunctiva. Results of all laboratory tests were within normal limits.

Discussion

DR ARNOLD KLEIN: Ligneous conjunctivitis was first described in 1933 by Borel.[1] The natural course of the disease involves the onset of acute pseudomembranous conjunctivitis at an early age, followed by the appearance of woody-hard, asymptomatic granulomas of the conjunctiva in adulthood. The acute conjunctivitis is frequently accompanied by nasopharyngitis, vulvovaginitis, and other systemic findings. It is a disease of chronicity; our patient had been observed for 44 years, while the patient of Verhoeff[2] was observed for 36 years. Ligneous means "woody-hard" and refers to the clinical characteristics of the chronic granulomas. This case has been recorded in the ophthalmologic literature by Spencer et al.[3]

DR INDIANER: The original cases of

ligneous conjunctivitis were classified as granulomas. The entire dermis in this patient was replaced by an eosinophilic homogenized amorphous material resembling amyloid. In addition, there was an inflammatory infiltrate with plasma cells, eosinophils, lymphocytes, histiocytes, and dilated and proliferating capillaries that contained thrombin. Endothelial cells were enlarged. Atypical fibroblasts were noted. Congo red stain was red in color, but when examined under polarized light the dichroism or shifting in color that is expected with amyloid was absent. With the crystal violet stain, the homogenized material was violet, and therefore negative for the metachromatic red color of amyloid. Can this represent colloid deposits, or porphyrin deposits? The patient had been treated with roentgen radiation, which can produce eosinophilic homogenized deposits of material with enlarged fibroblasts and vascular stasis. This would be a good case for electron microscopy in order to determine the exact nature of the deposit.

DR KLEIN: Another interesting finding in our patient is her exfoliative vaginal cytologic feature that initially appeared malignant, but subsequently, a cervical biopsy specimen showed a histologic pattern identical to the conjunctival granuloma and accounted for the suspicious cytologic pattern. We are dealing with an unusual systemic disease, rather than a simple conjunctivitis.

METROPOLITAN DERMATOLOGICAL SOCIETY OF LOS ANGELES

Nov 25, 1975 Robert I. Freedman, MD, Recorder

Hyperpigmentation of the Basal Layer. Presented by ROBERT FREEDMAN, MD; MANLEY COHEN, MD, FACP; ROBERT PARKE, MD

A 26-year-old Filipino woman complained of discoloration of her left leg. The lesion first appeared as a reddish discoloration at the left ankle in 1970 and progressed to involve most of the skin of the left leg between the ankle and the knee. Shortly after her arrival in this country in 1974, she was seen in the dermatology clinic of Harbor General Hospital. The initial diagnosis was linear scleroderma vs pretibial myxedema, and results of a punch biopsy were interpreted as "consistent with scleroderma (later stage)."

Admission to the Memorial Hospital of Long Beach was required because of cellulitis and superficial thrombophlebitis in the right calf. Results of physical examination showed the left calf to be heavily pigmented and warmer than the surrounding skin; it was covered with coarse, black hair, and it felt firm, although there was no pitting edema. A 2 × 4-cm tender left inguinal lymph node was present. A punch biopsy specimen taken from the left leg showed hyperpigmentation of the basal layer. Congo red stain for amyloid was negative.

The patient's menstrual history is of interest in that the cessation of regular menses was generally followed by swelling, tenderness, and warmth in the affected left leg, which may have lasted 24 to 48 hours. Her menstrual periods were normal, she was gravida 0, and had not received oral contraceptives. The medical history was unremarkable, particularly with reference to trauma, chronic infection, infestation, or ulceration.

Results of laboratory studies showed that complete blood cell count, liver enzymes, pancreatic enzymes, serum protein electrophoresis, serum calcium, serum phosphorus, and serum uric acid levels were normal. T_4 was 12.1 (normal, 4.5 to 11.5). Fungal culture of skin and potassium hydroxide preparation were negative. Roentgenograms of the right and left legs were normal, and results of an ultrasound examination of the left leg were normal.

Discussion

LEO INDIANER, MD: I was impressed by the prominent basalar zone pigmentation. The question clinically, is whether this was a Becker nevus with pigmentation and hair as the primary nevoidal event, or whether the pigmentation and hair increase were on the basis of an underlying vascular or metabolic process. I do not think the biopsy specimen really showed the hairs, to demonstrate if they extend deeper than they should in this particular area as compared with usual hairs on the opposite extremity. Neither was the biopsy specimen deep enough to exclude other causes, and the question was raised repeatedly as to whether there was a difference in temperature on this leg. This is either a nevoidal process that is primary, with a vascular component, or it is vascular, with the pigmentation and hair increases as secondary phenomena.

GEORGE GEMMINGEN, MD: This patient had the same number of hairs on both legs, which is important. If she had a Becker nevus, then she should have a difference in the number of hairs. Trichogenesis does not occur in people; in fact it does not occur in any animal, except maybe for in antlers of deer. I think that this woman has solid edema of her leg. It was a pitting type of edema, and she states that she has an enlarged lymph node in the groin. If she does indeed have a solid edema, then one must look for a chronic infection, or a lymphostatic process, or even a vascular anomaly of some sort. It might be worth doing a lymphangiogram or arteriogram.

MEYER BERKE, MD: Clinically, she has scleroderma and an accentuation of hairs that are already there. They are coarser, darker, and longer, much as in porphyria cutanea tarda.

STANTON MAY, MD: Each month, at the time of her period, this condition worsened considerably, with a good deal more swelling. Among the things to consider in the work-up would be an examination by a gynecologist to see if there is any disease in the pelvis.

DR FREEDMAN: I believed that this was an edema rather than a scleroderma. I would expect atrophy of the hair with scleroderma rather than the hypertrichosis that we saw. The hypertrichosis and the hyperpigmentation remind me of vascular process, such as erythema ab igne, that was reactivated time after time, along with the edema. The puzzling thing is that it is limited; it begins above the ankle and ends below the knee, whereas if this was a lymphedema with blockage in the inguinal area, one would expect to see the swelling extending up higher. It may be that the vessels are sensitive to estrogen or progesterone and become dilated at certain times.

Multiple Keratoacanthomas on Upper Extremities. Presented by WALTER S. GREEN, MD, LAURENCE J. UNDERWOOD, MD, ROLIN GREEN, MD

A 55-year-old woman first noted lesions on her forearm in 1969. Gradually, more lesions appeared, and larger areas became involved. Spontaneous regression was not noted, nor were the lesions symptomatic, except for tenderness if bumped. There was no family history of similar lesions, nor had she had a previously known viral or "wart" problem. There had been no exposure to tars or other chemicals or carcinogens, although the patient had used baby oil on her skin for years. Through the years she exposed her skin to much sunlight. She has had hypertension for many years, and at present is receiving spironolactone (Aldactazide).

On the dorsa of the hands, the knuckles, and the extensor surface of the arms and forearms were symetric plaques of pinkish papules and nodules. The larger lesions were elevated, dome-shaped, and had a crusted keratinous center. A biopsy specimen taken from the right forearm by her family doctor was interpreted by a general pathologist as a keratoacanthoma. A biopsy specimen from a 1.5-cm "growing" nodule of six weeks' duration was presented. The pathologic findings were those found in a keratoacanthoma, namely, substantial hyperkeratosis and, pseudoepitheliomatous hyperplasia, entrapping keratin masses and surrounded by a chronic inflammatory infiltrate.

For treatment, lubricants, intralesional injection of an unknown medication, kera-

tolytic "Freezone," and a limited trial of lactic acid-salicylic acid, 15% of each in collodion, and salivylic acid (Keralyt) under occlusion were used.

Results of a biopsy showed there was an epithelial proliferation in which masses of relatively mature squamous epithelium extended to the level of the reticular dermis. The squamous dysplasia was moderate. I do not believe that this was pseudoepitheliomatous hyperplasia of a reactive character. I would agree with the diagnosis of keratoacanthoma (Bernard Gottlieb, MD).

Discussion

MEYER BERKE, MD: For these lesions, I have used local triamcinolone acetonide liquid nitrogen with variable results. Many of them regress spontaneously. If any lesion gets too large. I would surgically remove it.

DR INDIANER: Other things that might be considered in the differential are swimming pool granuloma, bromoderma, iododerma, and reactive hyperplasia with folliculitis. One of the tests of the keratoacanthoma is that it comes and goes. If it does not go, then eventually some other etiologic factors may have to be looked for.

DR MAY: Assuming that the diagnosis of keratoacanthoma is correct, I suggest treating these lesions with tincture of podophyllin. I once presented a patient to the Los Angeles Dermatological Society who had a huge keratoacanthoma on her lip. Within a few weeks after I applied the podophyllin, this lesion miraculously cleared up.

STUART MARTEL, MD: The patient shows evidence of considerable sun damage. She spends every weekend at the beach and does not use any protective sun screen.

JOHN WATSON, MD: In addition to being a sun-lover, the patient has been taking two photosensitizing sulfonamides for ten years, namely saccharin for weight control and thiazides for essential hypertension. All sulfonamides should be avoided in patients with solar dermatoses.

STEVEN KARASSIK, MD: You might consider using immunotherapy with dinitrochlorobenzene; you would sensitize the patient to it and challenge the individual lesions with this immunogen.

The Case of the Vanishing Lesions: Mycosis Fungoides? Presented by VINCENT P. BURBY, MD.

This woman has had a variety of skin lesions since 1965. They arise, then disappear after a short period of time, but always present a diagnostic problem. The patient first had a yellowish-red, raised lesion on her forehead suspected to be a lymphoma. It disappeared spontaneously after the biopsy specimen was taken. In 1969, dull red annular lesions appeared on her hand, clinically resembling granuloma annulare. The biopsy examination was consistent with a diagnosis of premycotic mycosis fungoides. These lesions became eczematized and then disappeared. In 1970, lesions typical of erythema multiforme appeared on the right forearm. At that time, the patient was receiving Donnatal Plus. More lesions of the same type developed two weeks later after dental surgery was performed under thiopental sodium (Pentothal Sodium) anesthesia; atropine, meperidine (Demerol), hydrochloride and lincomycin hydrochloride monohydrate were also given at that time.

Her latest eruption occurred in October 1975. The lesions were shiny, raised, yellowish-red nodules on the dorsal surface of the hands and wrists. The biopsy specimen from the wrist was interpreted as suggestive of early parapsoriasis. Another specimen from a scaling, red lesion on the leg was interpreted as parapsoriasis, possible premycotic mycosis fungoides.

Results of a bone marrow study, done elsewhere, were reported to be normal. Results of a complete blood cell count were as follows: hemoglobin, 12.8%; hematocrit, 38%; erythrocytes, 4.11 million/cu mm; mean corpuscular volume, 93 cuμ; mean corpuscular hemoglobin, 31 $\mu\mu$g; mean corpuscular hemoglobin concentration, 33%; leukocytes, 9,200/cu mm; segmented neutrophils, 83%; lymphocytes, 17%; sedimentation rate, 39 mm/hr. Results of a biochemical profile ordered by her family physician were normal. Presently the patient has been receiving indomethacin (Indocin), methocarbamol (Robaxin), and conjugated estrogens (Premarin).

Discussion

DR INDIANER: Three slides were presented, all with a dense infiltrate of small and large lymphocytes and mononucleated cells within the dermis. One of the slides demonstrated pure hyperkeratosis and exocytosis of these cells into the epidermis. In the second biopsy specimen, there was a focal delicate parakeratosis with exocytosis of cells into the epidermis. The third slide showed hyperkeratosis, hypergranulosis, and a lichenoid type of infiltrate extending into the epidermis. Some of the lymphocytes were enlarged, but there were not clusters of these cells in the epidermis to a sufficient degree to be diagnostic of mycosis fungoides. The second biopsy specimen might be called a parapsoriasis-type subchronic dermatitis, while the third one could be classified as a lichenoid subchronic dermatitis. I would not agree that this is a malignant lesion. There are lesions that do resolve that are inflammatory, and also there is lymphomatoid papulosis, where you can have weird, atypical, bizarre cells. Also, Sezary-type cells or T-type cells under the electron microscope mimic those cells that you see in mycosis fungoides, yet the lesions resolve. I was not impressed with the atypia and would call this a dermatitis.

DR GOTTLIEB: I was impressed with the dermal-epidermal interplay in all biopsy specimens. I would put erythema multiforme and drug eruption at the top of my list.

DR MAY: These lesions occur only on the exposed extremities, and I wondered if this could be a polymorphous light sensitivity eruption, since it comes and goes so dramatically.

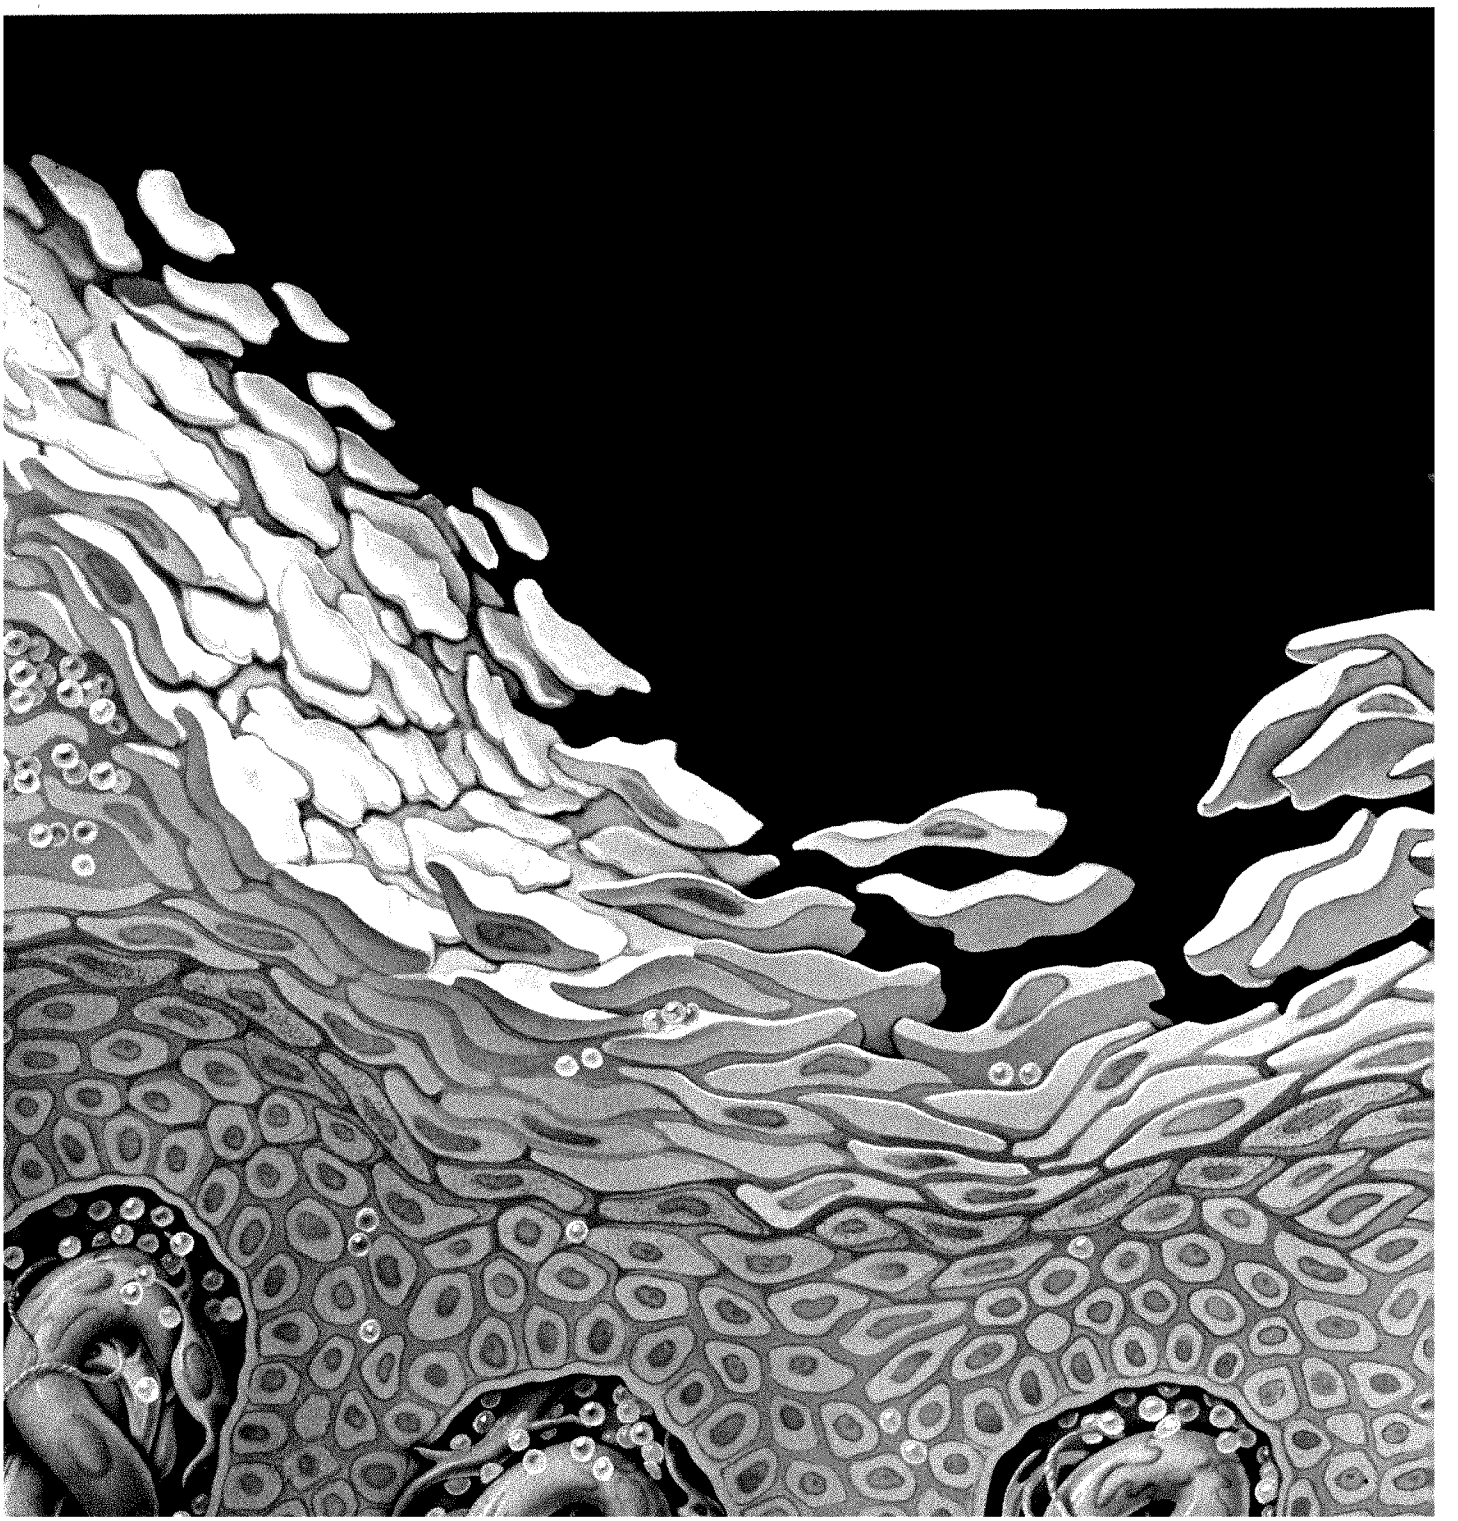
PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word can make an afflicted patient cringe. And, because of the capricious, unpredictable nature of the disease, the patient rarely knows where or when it will recur.

Obviously, the goal is control. And, though varied treatment modalities are available today, none offers universal



efficacy for all patients, all of the time.

Yet, very often a highly effective topical steroid, like Lidex, (fluocinonide) can help stabilize psoriasis.

Lidex. A highly effective topical steroid with anti-inflammatory, vasoconstrictive, antipruritic actions.

100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

SYNTEX

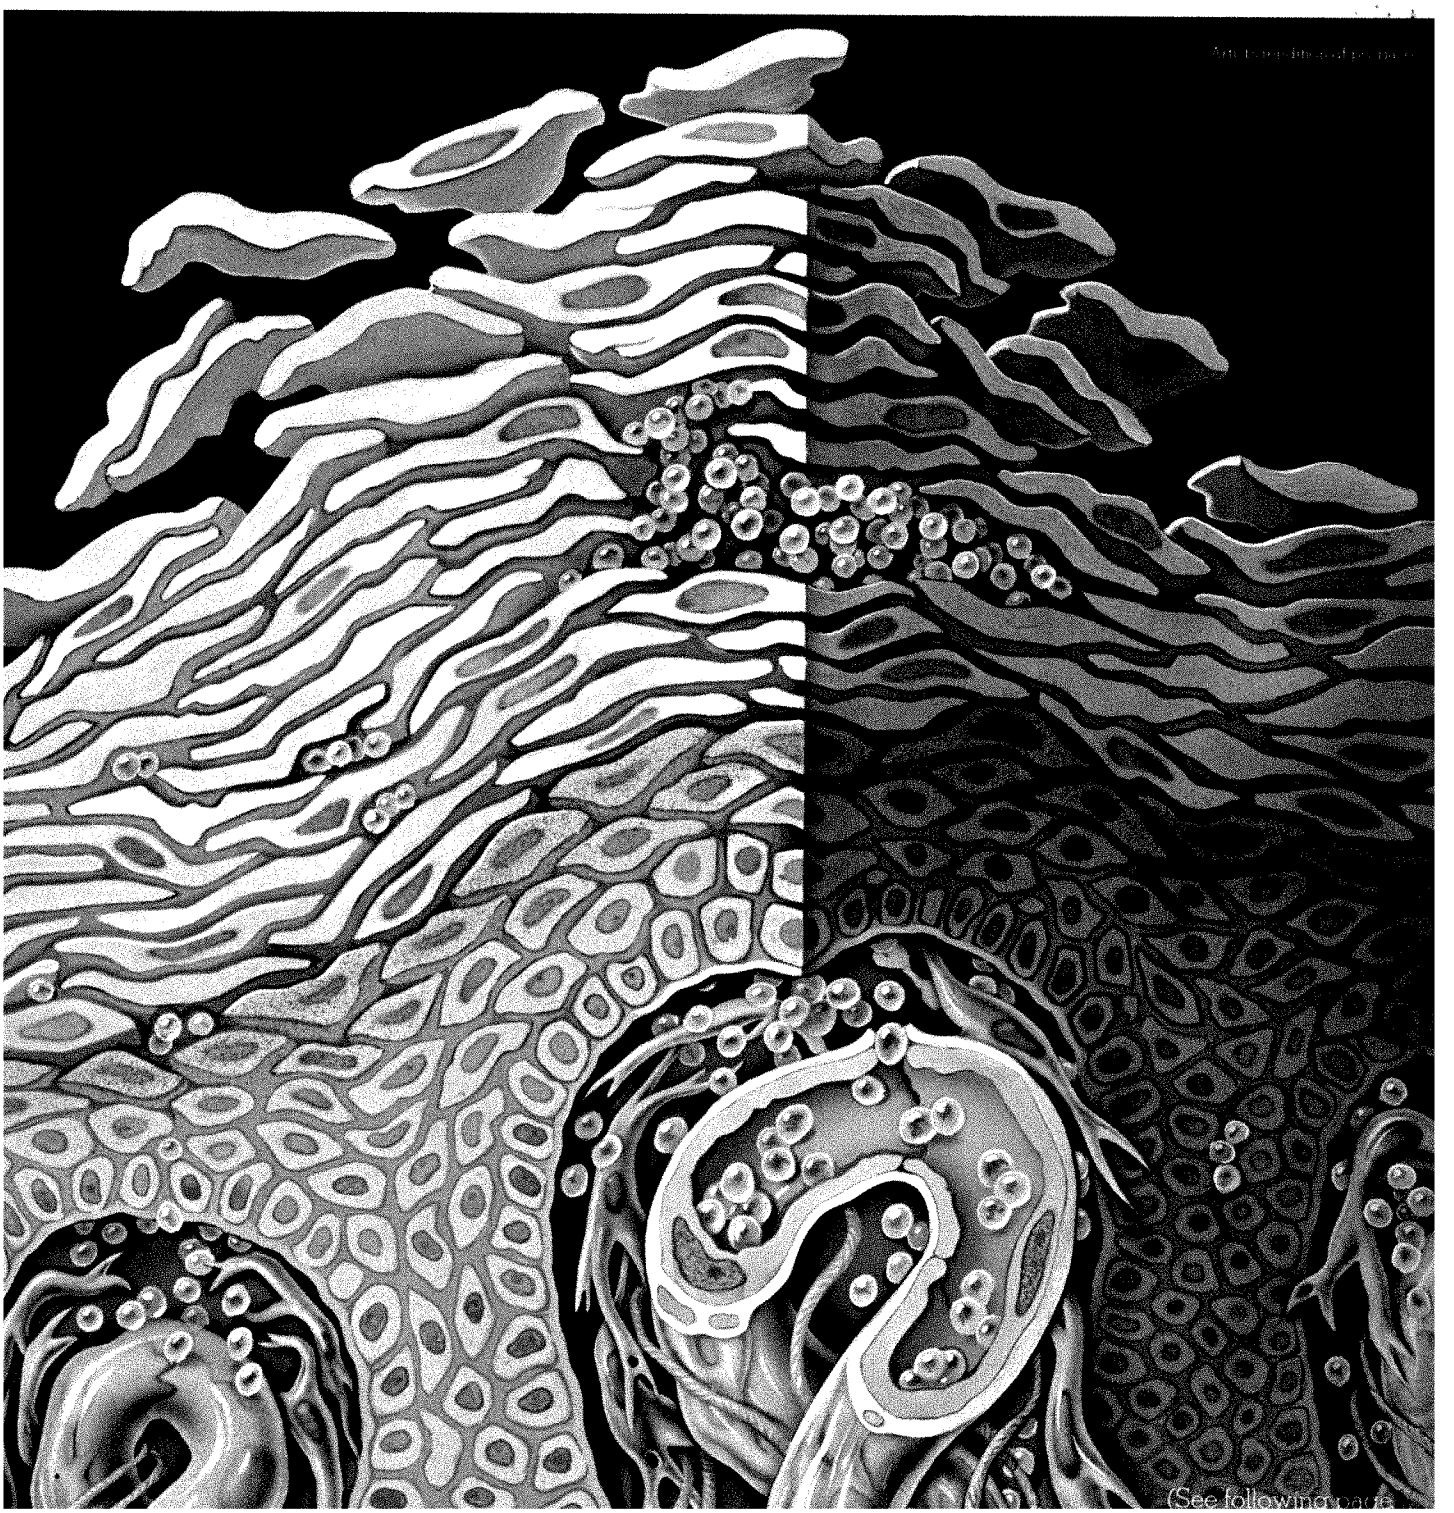
PALO ALTO, CALIFORNIA 94304



(See following page)

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

FDA soon to approve fat emulsions for clinical use!
Prepare yourself with this new AMA book...

Fat Emulsions in Parenteral Nutrition

A digest of the latest important research findings

FAT EMULSIONS IN PARENTERAL NUTRITION, the proceedings of the June, 1975 meeting sponsored by the Department of Foods and Nutrition and the Nutrition Advisory Group of the AMA, will provide you with a review of experimental and clinical studies and discussions of problems encountered with the use of fat emulsions.

Divided into three sections, the book covers the metabolism of fatty acids and function of essential fatty acids with information on EFA deficiency; fat as an energy source; and the pathophysiology with discussions on side effects, interrelations with other nutrients, and the current status of products available.

To avoid potential problems and to become thoroughly acquainted with the intricacies of this about-to-be-approved nutritional supplement, every hospital physician, nurse and pharmacist should make this publication required reading.

Order Dept. OP-140, AMA, 535 N. Dearborn St., Chicago, Ill. 60610

Please send _____ copy(ies) of FAT EMULSIONS IN PARENTERAL NUTRITION, OP-140, $7 in U.S. and U.S. Possessions, $7.50 elsewhere.

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

atients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—articularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

Letters to the Editor

Cutaneous Polyarteritis Nodosa

To the Editor.—Cutaneous polyarteritis nodosa is a benign disease that involves the deeper dermis and subcutis, muscle, and nerves, with only rare cases developing systemic involvement.[1] Remissions occur spontaneously[2] or following steroid therapy.[2-4] We here report a case associated with tuberculosis and responding to antituberculous therapy.

Report of a Case.—A 24-year-old man was admitted to the hospital because of weakness, pain, and swelling of both lower extremities, associated with painful erythematous nodules over the legs of about six weeks' duration. Some of these ulcerated and discharged necrotic material. He also had a 15-kg (33-lb) weight loss and fever. Eight weeks prior to admission, he had fever and an upper respiratory tract infection lasting ten days. He was a former heroin user but had been drug-free for the past 1½ years. On examination, he had a remittent fever, with a nightly rise in temperature to about 38.3 C (101 F). He was normotensive and had well-circumscribed, tender, nonulcerated subcutaneous nodules on both calves and in the pretibial area, without involvement of overlying skin. Small and shotty cervical, axillary, and epitrochlear lymph nodes were palpable. There was weakness of both lower extremities with right foot drop but no sensory loss. The right epididymis was painful and tender. The ESR was 112 mm in the first hour (Westergren); serum albumin value, 3 gm/100 ml; globulin, 4.7 gm/100 ml; γ-globulin, 2 gm/100 ml; VDRL test, positive at 2+; latex fixation test, positive at 1:160; antinuclear antibody test, negative; febrile agglutinins (OX-19), positive 1:160; and anti-streptolysin O (ASO) titer, 333 Todd units. The WBC count was normal. The purified protein derivative skin test for tuberculosis was strongly positive, with sloughing of the reaction site. The reaction had been negative six months earlier. The patient admitted contact with an active case of tuberculosis.

A subcutaneous nodule and a muscle biopsy specimen from the right calf were submitted for histological examination.

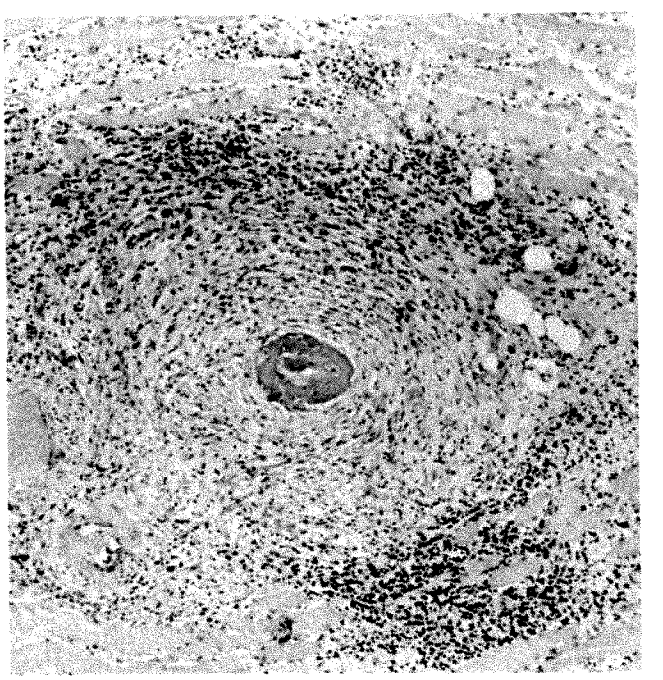
Histological Findings.—A necrotizing inflammatory process was found, involving a small muscular artery in the subcutaneous tissue (Fig 1). The necrosis was eccentric, destroying the entire thickness of the arterial wall and producing a pseudoaneurysm. Polymorphonuclear leukocytes were found in this area. The lumen was occluded by a fresh thrombus. A limited chronic inflammatory reaction was present immediately surrounding the vessel. Panniculitis was minimal and a solitary ill-formed, nonnecrotizing granuloma was present in this area. The muscle contained a thrombosed vessel, with complete replacement of its wall by macrophages, fibroblasts, and a few lymphocytes (Fig 2).

Treatment was started three weeks after admission with penicillin G benzathine (Bicillin), 2.4 million units intramuscularly twice daily on the first and seventh days, isoniazid, 300 mg daily; and rifampin, 600 mg daily. Within ten days, the skin lesions regressed and he became afebrile. The serum globulin two months later was 2.9 gm/100 ml. Now one year later, the patient is still receiving antituberculous therapy but has had no recurrence or residua of the arteritis or epididymitis.

Comment.—The etiology of cutaneous polyarteritis nodosa remains obscure. One patient in Borrie's[3] series of 15 cases had pulmonary tuberculosis and developed the arteritis two months after beginning a nine-month course of streptomycin sulfate. Since the lesions regressed in the presence of continuing streptomycin therapy, it is probable that they were causally related to tuberculosis rather than to the drug. Cutaneous polyarteritis nodsa responding to penicillin has been reported in associa-

Fig 1.—Muscular artery in subcutaneous tissue, showing mural and perivascular leukocytic infiltrate, thrombosis, partial destruction of internal elastic lamina, and eccentric destruction of media with formation of pseudoaneurysm (arrows) (Weigert elastic stain and hematoxylin-eosin, ×50).

Fig 2.—Blood vessel in gastrocnemius muscle, showing total destruction of vessel wall, transmural and perivascular infiltrate of macrophages, lymphocytes, and fibroblasts, and thrombus occluding lumen (hematoxylin-eosin, ×50).



tion with streptococcal infection.[3-5] The raised ASO titer suggests that the initial respiratory infection was streptococcal.

The time lag of ten days between the onset of therapy and the regression of the lesions is strong evidence for a cause-and-effect relationship. For a necrotic, thrombosed muscular artery of the size involved in this case to organize, recanalize, and become functional again, a time requirement of one to two weeks seems entirely reasonable. It is not possible to state unequivocally which of the two modalities of therapy, penicillin or antituberculous drugs, was responsible for the remission. Our personal bias is for the latter, in view of the stronger evidence of active tuberculous than of any other infection in this patient.

Nonathletic Calcaneal Petechiae

To the Editor.—A black spot developed on my right heel in December 1975, at which time I was not engaged in any athletic activity. The lesion persisted for several months and spontaneously cleared.

Recently (August 1976), I had difficulty in getting into my shoes, I recalled similar trouble with the same shoes when the black spot appeared.

It seems that trauma, athletic or otherwise, may cause calcaneal petechiae.[1]

Lichen Planus and Xanthoma

To the Editor.—The development of unusual changes in hypertrophic lichen planus may indicate the development of epitheliomatous change. We wish to report a case of hypertrophic lichen planus that changed its clinical appearance as a result of underlying xanthoma formation.

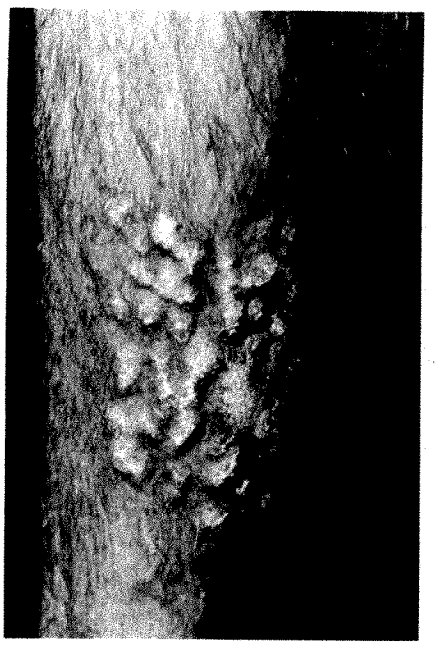

Fig 1.—Lesion on right leg.

Report of a Case.—A 33-year-old man was referred to Royal Brisbane Hospital in 1969 with recurrent bouts of jaundice, abdominal pain, and fevers. A cholecystoduodenostomy was performed to relieve a strictured common bile duct. He remained well until 1972 when he presented with recurrence of his symptoms. He was noted to have a large plaque of hypertrophic lichen planus on his right shin with smaller areas on the left. These had been present for two years. The diagnosis was confirmed by biopsy. Mild diabetes mellitus and chronic pancreatitis had also developed. A further drainage procedure was carried out on his common bile duct. When next seen in 1975 with recurrent cholangitis, he reported recent thickening of his plaques of lichen planus (Fig 1). Biopsy revealed numerous foam cells in the upper and mid dermis with overlying lichen planus (Fig 2). There were no xanthomata present elsewhere, although his serum cholesterol level was 656 mg/100 ml; triglycerides, 685 mg/100 ml; and there was a type II B electrophoretic pattern. There has been some decrease in the size of the skin plaques and improvement in his biochemical values following further surgery to the common bile duct.

Comment.—Animal experiments suggest that the primary factor determining the distribution of xanthomata in hyperlipidemic states is local increase in vascular permeability perhaps determined by the release of vasoactive substances at sites of trauma! Vascular permeability could also be increased in an area of skin

Fig 2.—Xanthoma cells with overlying hypertrophic lichen planus (hematoxylin-eosin, ×65).

previously affected by a dermatosis. While there has been a report of skin xanthomata following erythroderma and long-standing atopic eczema,[2] we know of no reports of a xanthoma developing preferentially in a plaque of hypertrophic lichen planus.

Tinea Versicolor

To the Editor.—Through the years, up until six years ago, I have examined the skin of a few hundred college football players and many fewer basketball players as part of their preschool-year physicals at the University of Kentucky. Beyond doubt, other than acne, the most common affliction in these athletes was tinea versicolor, with perhaps a majority having the disease, and often an accompanying tinea cruris or tinea pedis and, rarely, toenail tinea as well.

The number infected and the extent varied directly with the number of years of athletic participation, the incoming freshmen players being the least afflicted by the now culturable *Malassezia furfur*.[1-3] However, it was noted that even those with but

minimal involvement about the chest or shoulders often revealed a small, typical, fine scaling, pink to tan yellowish macule or two in the upper portion of the pubic hair as did virtually all of those heavily infected. Here then are four reasons for the high rate of relapse or reinfection in college athletes: (1) an inherent relative inability to resist infection by superficial fungi; (2) failure to treat the relatively hidden focus in the upper pubes, which reinfects the other skin areas and clothing; (3) an everburgeoning number of organisms in the athletes' environment; including towels, linens, uniforms, and equipment; and finally (4) the antigenically proved relationship of *M furfur* to the normal saprophytic yeast *Pityrosporon ovale* present on lipid-rich areas of the skin which in favorable, little-known circumstances may transform into the pathogenic *M furfur*.

Two novel cellular reactions induced by *M furfur* have been reported: (1) extracellular glycogen deposits in the upper epidermis[4] associated with increased stratum corneum turnover and (2) macromelanosomes in the lower epidermis in hyperpigmented tinea versicolor, singly distributed in the keratinocytes and hypermelanized. This latter effect is in direct contradistinction to the cutaneous effect of the fungus when it produces hypopigmentation (usually in sun-exposed areas) where it appears that production of abnormally small melanosomes is induced that are not properly transferred to keratinocytes.[5]

Onycholysis Through Phototoxicity

To the Editor.—Onycholysis through a phototoxic mechanism, in patients taking a tetracycline derivative, was described by Orentreich et al[1]. The following is a report of an unusual manifestation of this reaction.

Report of a Case.—A 20-year-old undergraduate had painful, swollen fingertips. One week earlier, she had experienced paresthesias in both hands, which had lasted a full day. Two days prior to her visit, her left fourth fingertip became tender and edematous; by the next morning, all fingers, except the thumbs, were similarly involved. There was no history to suggest contact dermatitis or trauma. Apart from studying, her activities included only sunbathing, which she does frequently, and has always tolerated well. Current medications were limited to levothyroxine sodium (Synthroid) (dose unknown) and tetracycline hydrochloride, 250 mg/day, taken for two years.

The patient was well tanned and healthy-appearing, and had edematous fingertips. The nail beds were pale, and the nail plate was raised up 2 mm from the hyponychium, without distal or lateral detachment (Figure). The nail was extremely sensitive to pressure. Her thumbs and toenails were spared, the latter being covered with nail polish. There was no other evidence of an acute sunburn reaction.

A shallow puncture was made with a No.12 Bard-Parker scalpel blade just below each nail plate, and clear, colorless fluid poured out freely. This maneuver relieved her discomfort considerably. Air bubbles could then be moved across the full area of the nail bed, indicating complete detachment to the proximal and lateral nail folds.

Comment.—Frank et al[2] reported three cases of tetracycline-induced photo-onycholysis. Two of their patients were taking tetracycline hydrochloride for 4 to 12 months, and at least one had a fair complexion. All showed sunburn elsewhere, as did the patients in the article by Orentreich et al.[1]

The two patients with photoonycholysis and discoloration described by Kestel[3] and the one by Bettley and Samman[4] were taking tetracycline (Achromycin) and demeclocycline hydrochloride, respectively. None had other signs of acute sun injury. The discoloration was considered secondary to hemorrhage. In a study by Frost et al,[5] 12 of 13 patients taking demeclocycline experienced paresthesias within 48 hours of their initial sun exposure.

This patient is unusual in that photosensitivity reactions to tetracycline are much less common than with its cogeners. Furthermore, she had previously had significant exposure to sunlight while taking the medication and had no adverse affects. The patient's deep tan may explain the localization of the reaction to her nails. The toenails were protected by polish but one must presume that the thumbnails were less exposed because of their positioning.

The nailplate is a poor sunscreen and may even concentrate solar radiation.[1] The incomplete separation of the nailplate from the bed, induced by the buildup of fluid, may be an initial

Nailbeds of patient with onycholysis.

stage of a more typical onycholysis that did not proceed to completion. Perhaps this is a clue to the mechanism of onycholysis in photosensitivity reactions.

An Aqueous Solution?

To the Editor.—I am not really enlightened by Bernard Ackerman's reply to Dr Samuelson's query in the July ARCHIVES (111:925, 1975). If the antigens were "suspended in an aqueous solution," one immediately wonders "a solution of what?" If it was a solution of nothing or if the antigens were not in fact suspended, but dissolved, then it would have been best to come right out and say "water" instead of an aqueous solution—if water is what was meant.

Dermatolipidectomy of Elephantiasis Nostras Verrucosa of the Panniculus

To the Editor.—In 1973, Rudolph and Gross reported in the *Archives of Dermatology* (108:832, 1973) a case of elephantiasis nostra verrucosa of the panniculus. An etiology of obesity, repeated episodes of erysipelas, and chronic passive congestion was proposed.

During the past three years, the patient had been receiving erythromycin and had been free of cutaneous infection. In spite of stable weight, the massive abdominal apron had become a physical and social problem (Fig 1).

The patient recently was operated upon for relief of her physical complaints. An abdominal dermatolipectomy was done, with resection of 6.8 kg of fat, scarred subcutaneous tissue, and the plate of verrucoid skin (Fig 2). Significantly enlarged vascular channels were found supplying this dependent tissue mass. Primary wound healing was achieved, and the patient obtained marked relief.

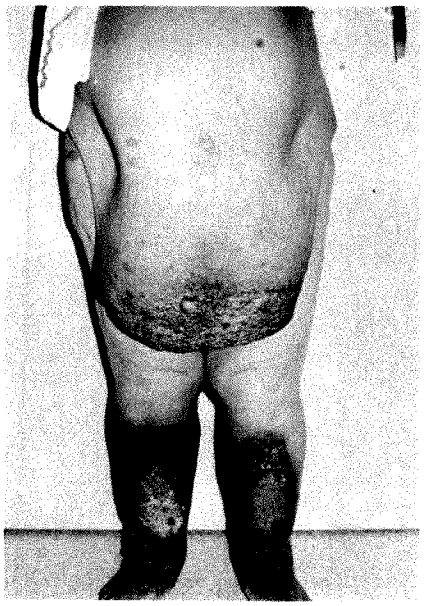

Fig 1.—Elephantiasis nostras verrucosa of panniculus. Note verrucoid pattern of abdominal skin.

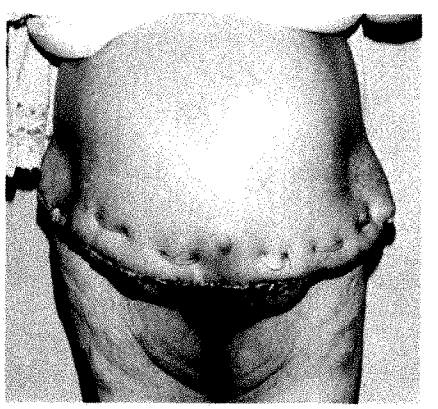

Fig 2.—Early postoperative view. There was no evidence of visceral herniation.

Report on Levamisole Hydrochloride for Warts

To the Editor.—Levamisole hydrochloride, an antihelminthic, has been reported as a successful method for treating resistant warts.[1] In view of the difficulty of treating some patients with persistent recurring warts, it seemed worthy to further pursue the evaluation of levamisole for this indication. Ten patients from my private practice who have a history of chronic, resistant warts were entered into the study. However, two were lost to follow-up and were therefore deleted from all tabulations and analyses. Of the remaining eight patients, four were male and four were female. The ages ranged from 7 to 57 years.

Response to Levamisole

Patient	No. of Warts Pretreatment	No. of Warts Posttreatment
1	15	1
2	4	1
3	3	0
4	13	22
5	16	0
6	6	6
7	15	0
8	10	20

Each patient was instructed to take 150 mg of levamisole hydrochloride on two consecutive days a week. The patients were treated for periods up to seven months. Of the eight patients entering the study and completing treatment, three had complete regression of their warts. Two other patients had a significant beneficial effect from the levamisole therapy (Table). Two of the patients who did not respond were clearly obese and may have been underdosed. The third patient who had no response was a 27.6-kg, 7-year-old child who actually had an increased number of warts. This patient may have been overdosed. The only adverse reaction reported was stomach cramps in one patient who was unable to continue the therapy.

The natural history of warts is one in which spontaneous regression can occur. It is also known that there can be a significant placebo effect. However, all the patients in this study have suffered from warts for one to six years and had previously been treated for 4 to 21 months with conventional therapy. More studies, particularly double-blind studies, are necessary to evaluate the effectiveness of levamisole in the treatment of this common dermatologic condition.

"The First Report of. . ."

To the Editor.—"To the best of our knowledge, this is the first report of . . ." is one of those hackneyed phrases that evokes a yawn from the average medical journal reader. If the claim is unjustified, a sense of mild irritation may accompany the yawn. The recent article by Campo and McDonald (112:687-689, 1976) elicited such a reaction. Contrary to the self-serving statement of these authors, Neldner and Hambridge published the first report of the successful treatment of acrodermatitis enteropathica with zinc sulfate in the US literature (*N Engl J Med* 292:879-882, 1975). Since this report appeared prior to the publication acceptance date of the article by Campo and McDonald, there was plenty of time for these authors to amend their final manuscript prior to actual publication.

Not satisfied with trying to be "first in the US," Campo and McDonald seek even greater glory by proudly proclaiming that their paper is "possibly the second formal case report in the world literature" describing successful treatment of acrodermatitis enteropathica with zinc sulfate. The authors apparently consider Moynahan's 1974 report of nine patients so treated as "informal" and therefore unworthy (*Lancet* 2:399-400, 1974). Nevertheless, they overlooked a "formal" paper published one year ago, describing five patients with acrodermatitis enteropathica successfully treated with zinc.

Contributors to medical journals should address themselves to the question, "what's important?" not "who's first?" Treatment of acrodermatitis enteropathica with zinc *is* important; who was "first in the US" or "second in the world" to use this treatment is not.

DAVID A. VORON, MD

Chondrodermatitis Nodularis

To the Editor.—Chondrodermatitis of the ears was first described by Winkler[1] in 1915 under the title of "Chondrodermatitis Nodularis Chronica Helicis." The lesions described in that study were small painful nodules with central crusts. The first report in the American literature was Foerster's[2] in 1918 that reported painful nodular growths on the helix of the ear. Since these original case descriptions, further case reports have shown this lesion to be characterized as a painful nodule that occurs primarily in patients older than 40 years of age and rarely occurs before one is 20 years of age. Men are involved in approximately 90% of the cases in which the lesions occur predominantly located on the helix of the ear. Less common sites include the antihelix, tragus, concha, and the antitragus. This entity, infrequently described in women, seems to occur more often on the antihelix than on the helix. This observation has led some investigators to believe that the pathogenesis of these two lesions is different.[3]

I have recently treated a patient from whom a biopsy specimen was taken that proved chondrodermatitis nodularis, as interpreted by Dr. Daniel Richfield, and report it because of its unusual nature. The patient was an 18-year-old, white woman who had a four-month history of a completely asymptomatic nodule on the superior posterior aspect of her right ear. The lesion was a firm nodule that had a central crust that on removal yielded a small, well-defined ulcer that was nontender. Biopsy of the nodule revealed the diagnosis of chondrodermatitis nodularis. I report this interesting case because of the unusual location, the asymptomatic nature, and the early onset in an adolescent female.

Penetration of Topical Steroid Preparations

To the Editor.—We read with interest the comments of Drs Lee and Rapp in your columns (*Arch Dermatol* 112:261, 1976). We agree with them that increased percutaneous penetration and increased potency of topical corticosteroids will not solve all the problems of inflammatory skin disease. It has long been recognized that increased percutaneous penetration leads to adverse systemic effects such as suppression of the hypothalamic-pituitary-adrenal (HPA) axis, although this has so far been observed mainly in children, adults with extensive inflammed skin, or adults treated with occlusion.

Recently, a new topical corticosteroid, clobetasol propionate (Dermovate cream and ointment [Britain]) has been marketed in this country. It was found to be extremely effective and is now widely used. However, after a period, cases of pustular psoriasis began to appear, generally following cessation of treatment with this preparation. Some patients were clinically Cushingoid and showed evidence of adrenocortical insufficiency on withdrawal of the topical corticosteroid, even though occlusion had not been used. These patients were shown to have pituitary-adrenal axis suppression.[1] This is analogous to the appearance of pustular psoriasis on withdrawal of systemic corticosteroids.[2]

Impressed with the potency of this corticosteroid formulation, we examined its effect on volunteers with normal skin; 12.5 gm of the cream applied to half the body surface area without occlusion was sufficient to produce profound HPA axis suppression in the majority of subjects.[3] We concluded from data on patients and normal volunteers that the "safe" weekly dose of clobetasol propionate is less than 50 gm.

We believe that the search should not be for increased potency and percutaneous penetration. It is essential to discover whether the effect on the epidermis and dermis may be separated from each other and from the systemic effects. Glaxo Laboratories Ltd, the manufacturer of Dermovate, have recently reported an attempt to do this with clobetasone butyrate (Molivate), although this assertion has yet to be proved in clinical practice. We think this is a more fruitful line for future investigations.

Demonstration of Herpes Virus by Electron Microscopy in the Crust of a Healing Lesion of Eczema Herpeticum

To the Editor.—The diagnosis[1,2] of eczema herpeticum can be confirmed or supported by demonstration of multinucleated epithelial giant cells in Tzanck cytological smears prepared from vesicular lesions; by demonstration of herpes simplex virus (HSV) particles by electron microscopy in phosphotungstic acid-stained material obtained from vesicle contents and base scrapings; by demonstration of multinucleated epithelial giant cells with eosinophilic intranuclear inclusions in biopsy specimen sections processed for light microscopy; by demonstration of HSV particles in biopsy specimen sections of vesicular lesions prepared for electron microscopy; by demonstration of direct culture of HSV from the lesions; by demonstration of HSV antigen in biopsy specimen sections by means of fluorescent antibody; or by demonstration of a rise in titer of HSV-specific antibody in the blood.

With the exception of the last method, fresh lesions are required for these diagnostic demonstrations since older herpetic lesions often yield negative results. The most frequently used diagnostic techniques have been the first three as listed.

We here report a case of widespread eczema herpeticum on the face and trunk of a 73-year-old woman with mycosis fungoides in whom only nonvesicular 3- to 4-mm crusted lesions were available for examination and where the diagnosis was established by electron microscopic demonstration of numerous HSV virions only in the crust of a healing lesion. In this case, Tzanck smear, electron microscopic examination of phosphotungstic acid-stained scrapings from the base of the lesions after removal of crusts, viral cultures, and examination of hematoxylin-eosin-stained biopsy specimen sections by light microscopy all failed to establish the diagnosis. The HE-stained sections revealed a regenerating epidermis covered with a purulent crust. A few grouped pyknotic nuclei (Fig 1) in the crust resembled degenerating multinucleated epithelial giant cells. The regenerating epidermis and hair follicles did not show multinucleated epithelial giant cells. A moderately dense inflammatory infiltrate in the dermis consisted of lymphocytes, histiocytes, neutrophils, a few plasma cells, and a few large, somewhat atypical mononuclear cells along with cellular debris.

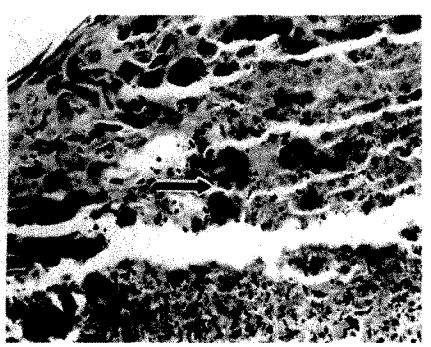

Fig 1.—Light micrograph showing grouped pyknotic nuclei (arrow) in crust of healing lesion (hematoxylin-eosin, original magnification × 500)

However, in the biopsy specimen sections prepared from a crusted lesion for electron microscopy, numerous HSV virions, many surrounded with envelopes, were observed only in the crust (Fig 2), the remainder of the epidermis and dermis being free of virus particles.

The purpose of this communication is to point out that even old crusted herpetic lesions can be used for definitely diagnostic demonstration of virus particles if crusts processed and sectioned for electron microscopy are examined.

Supported in part by a grant from the American Cancer Society.

Allergic Reactions to Chocolate

To the Editor.—I am interested in finding the incidence of allergic reactions to chocolate because of a recent query I received from a chocolate manufacturer.

I would appreciate hearing from physicians the estimated number of their patients who are allergic to chocolate, and the symptoms produced. I would also appreciate receiving specific case reports, results of laboratory tests, and any other comments on the subject.

CLAUDE A. FRAZIER, MD

Viral Hepatitis Type B

To the Editor.—Since viral hepatitis type B is a major public health problem in the United States, the reevaluation of dermatological office procedures seems to be in order. Hepatitis B was formerly called serum hepatitis and was thought to be transmitted only by parenteral routes such as inoculation or blood transfusion. Recent evidence indicates that viral hepatitis type B can enter the body orally through mucous membranes or per cutaneously. Minute fissures of the hands could easily be a source of entrance of the virus. It is not an uncommon practice to perform various surgical procedures without

gloves, including the curettement of warts, basal cell carcinomas, and incision and drainage of acne lesions. A good source with regard to the epidemiology of viral hepatitis type B, particularly in health personnel, is a supplement on the control of viral hepatitis type B found in *Morbidity and Mortality Weekly Report* (25 (17): May 1976).

It is my contention that the dermatologist should wear disposable gloves with all surgical procedures, both for the protection of the patient if the physician might unknowingly be a viral hepatitis type B carrier, or obviously to protect the physician himself.

EDWARD M. MOSS, MD
Fresno, Calif

Pro and Con of Continuing Education

To the Editor.—There has been much discussion pro and con in regard to continuing education, self-assessment examinations, and recertification of board-certified dermatologists. Most of the efforts seem to be centered around the concept of "boning up" on the more academic and scholarly aspects of the ever-expanding developments in our specialty. We are enthusiastically in favor of these efforts to keep the troops in top form. There are, however, two sides to this coin. We think that while we as humdrum daily practitioners and bearers of the colors brace ourselves for the coming educational ordeal, it would only be fair that those who dedicate their lives to teaching and research and the care of only a few patients a day share in the fun and games.

What we are proposing is that those primarily engaged in research and teaching in turn be examined on their knowledge and ability in handling the large parade of mundane acne, wart, and hand eczema cases. We suggest that these individuals slip on a smock and for a week, nay even one day, and get into the trenches where the action really is. The private practitioner would, of course, serve as the peer evaluator and perforce come up with some sort of value judgment on the examinee's ability to handle the realities of the practice of dermatology.

It is all very well to say, as some have done recently, that the dermatologist should leave the warts and acne to the "primary" practitioner. Let's face it, *mes enfants*, we are now, willy nilly, practicing primary dermatology whether we like it or not. All of us in active practice, as our plantar calluses thicken, our fingers tingle with writers cramp, and our voices turn raspy with overuse, conjure up visions of the ideal practice—a relaxed armchair approach to some difficult and challenging referral, with adequate time to prove the nuances of the situation. But, alas, the harrassed family practitioner, an endangered species in our area, when presented with any (we underline any) skin case smilingly shrugs his shoulders, proudly proclaims his total ignorance of the field, and faster than one can say "chondrodermatitis nodularis helicis chronica" shuttles the patient to his friendly dermatological colleague who always seems able to work in "just one more."

We need to ask ourselves some questions. How important is it to treat our average run of patients with acne and warts with skill and dispatch? How much time do we allow for the difficult complicated situation while squads of angry eczema and psoriasis cases crowd our waiting rooms in frustrated impatience? Do we burden the already crowded hospitals with these toughies and spend the remainder of a hectic and exhausting day meticulously working them up? We speak now of brownie points for attending seminars and medical meetings and we consider the imperatives of accumulating thus and so many credits to maintain our peer standing. Shall we have no time now for simple vacations? Or will we consider ourselves fortunate just to get to enough busman's holidays at medical conclaves during the year to stay current?

We, the undersigned, do make an effort to keep up with things within the limits of our abilities. We do go to some meetings; we do read journals; we do listen to tapes; we do discuss cases even though we may not carry in our minds the classification of the xanthomas. The subtleties of the HLA antigens and the complement cascade may not spring automatically to our lips, but we have the references in our private library and we know where and how to find them.

Think about it.

FULVICIN-U/F® Tablets brand of griseofulvin (microsize) tablets, U.S.P.
CLINICAL CONSIDERATIONS—
INDICATIONS Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), *Tinea versicolor*, Nocardiosis.
CONTRAINDICATIONS This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.
WARNINGS **Prophylactic usage:** Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established.
Animal toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in pregnancy: The safety of this drug during pregnancy has not been established.
Animal reproduction studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
PRECAUTIONS Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system functions, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
ADVERSE REACTIONS When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate counter-measures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if graulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
AVAILABLE in 125 mg., 250 mg., and 500 mg. scored tablets.
010 AUGUST 1973

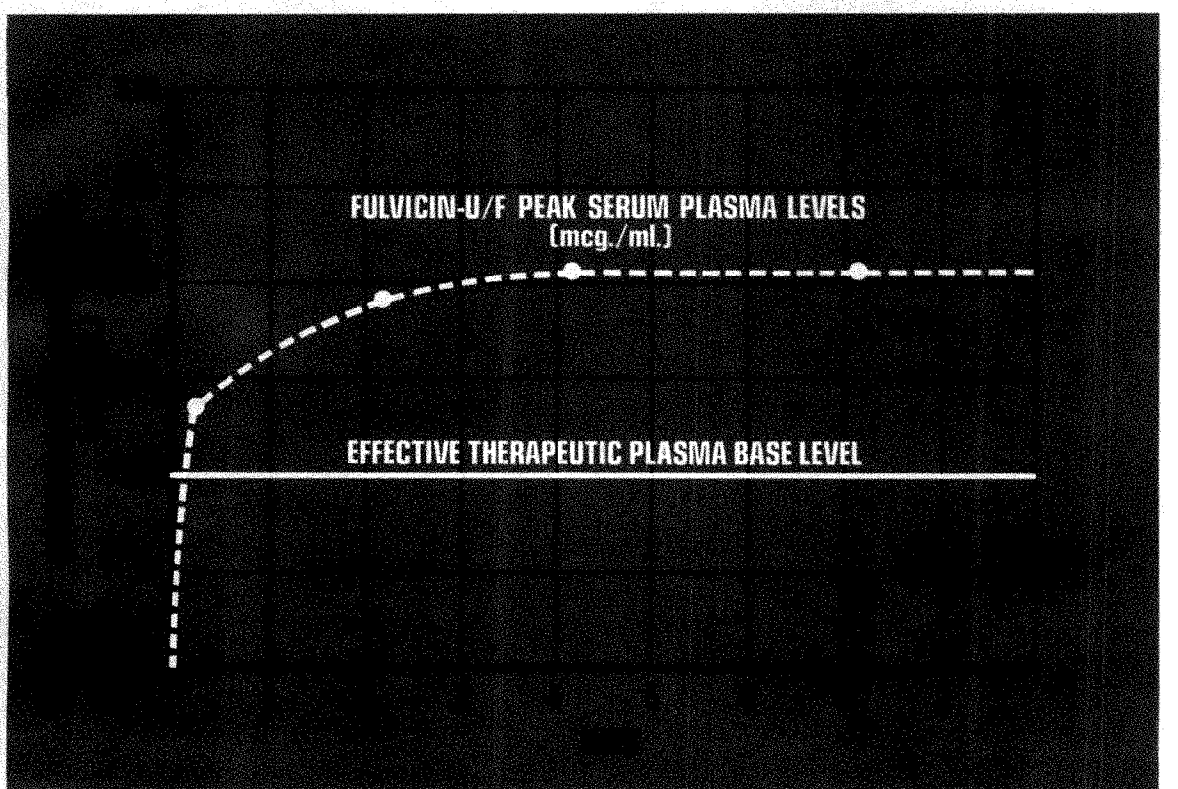
SUSTAINED THERAPEUTIC PLASMA LEVELS WITH ONLY ONE TABLET A DAY

Schering



Adapted from Symchowicz, S., and Katchen, B.: J. Pharm. Sci. 57:1383, 1968.

The above graph depicts average peak serum plasma levels of FULVICIN-U/F following once-daily dosage of one FULVICIN-U/F 500 mg. tablet given before breakfast to six normal subjects for a seven-day period.

Hours of fungistatic action at ringworm sites

The above graph on plasma levels of FULVICIN-U/F 500 mg. in once-daily dosage indicates that this dosage is adequate to keep the antibiotic available for antifungal action in the keratin precursor cells where fungi have invaded. With the growth checked by the fungistatic action, the fungi are cast off as the keratin grows out and sloughs off. Healthy tissue replaces infected keratin of skin, hair, and nails.

Clinical efficacy, safety, and convenience

The Ultra-Fine form of FULVICIN®—in clinical use for over 15 years—possesses two vital keys to success in long-term ringworm therapy: product familiarity, and the confidence that comes after years of effective and safe therapy. For your patient: dosage simplicity. The easy-to-remember, once-a-day routine that helps avoid dosage delinquency and the possibility of therapeutic setbacks when therapeutic plasma levels are not maintained.

Sulfoxyl® Lotion Regular ℞
Sulfoxyl® Lotion Strong
Composition: Sulfoxyl Lotion Regular contains 5% benzoyl peroxide and 2% sulfur; Sulfoxyl Lotion Strong contains 10% benzoyl peroxide and 5% sulfur, each in a lotion base formulated with polyethylene glycol monostearate, stearic acid, glycerol monostearate, isopropyl palmitate, propylene glycol, zinc soap and purified water.
Indications: Use as a topical aid in the treatment of acne.
Dosage and Administration: After cleansing the skin, smooth Sulfoxyl Lotion gently into the affected areas, once daily for three days. If no discomfort is felt, frequency of application can then be increased to twice daily. The amount of drying and desquamation can be modified by adjusting the dosage schedule.
Contraindications: Patients with a known sensitivity to benzoyl peroxide, sulfur or any of the other formulation ingredients should not use these medications.
Precautions: For external use only. Avoid contact with eyes, mucous membranes and sensitive areas of the neck. Notify physician if excessive dryness or irritation occurs or increases.
Keep from heat.
Caution: Patients should be warned that these formulations may bleach colored linens, towels and apparel.
How Supplied: 1.0 ounce plastic bottles.
Caution: Federal law prohibits dispensing without prescription.

Benoxyl® 5 and 10 Lotion: Benoxyl 5 contains 5% benzoyl peroxide and Benoxyl 10, 10% benzoyl peroxide in a grease-free washable lotion base.
How Supplied: 1 oz. and 2 oz. plastic bottles.

PanOxyl® 5, PanOxyl® 10 ℞
Composition: PanOxyl 5 contains 5% Benzoyl Peroxide. PanOxyl 10 contains 10% Benzoyl Peroxide. PanOxyl 5 and PanOxyl 10 also contain 6% polyoxyethylene lauryl ether and 40% ethyl alcohol in a gel base formulated with colloidal magnesium aluminum silicate, hydroxypropylmethylcellulose, citric acid and purified water.
Action and Uses: The topical use of PanOxyl 5 and PanOxyl 10 provides therapeutic control of acne through drying and desquamative action, as well as providing antiseptic activity.
Indications: Use as an aid in the treatment of acne.
Dosage and Administration: Apply 1 or more times daily to affected areas. Washing the face with soap and water prior to application greatly enhances the efficacy of the medication.
Contraindications: Patients with a known sensitivity to Benzoyl Peroxide should not employ these medicatons.
Precautions: For external use only. Avoid contact with the eyes or mucosal membranes. Very fair individuals should always be started on a single application at bedtime, allowing the medication to remain on the skin overnight. PanOxyl may bleach colored fabrics.
How Supplied: 2 oz. and 4 oz. plastic tubes.
Caution: Federal law prohibits dispensing without prescription.

Th. ee Dimensions of Acne Care

The widest range of benzoyl peroxide formulations gives you maximum therapeutic flexibility

New Sulfoxyl® Lotion

The drying and desquamating effects of sulfur added to benzoyl peroxide can be particularly valuable in acne complicated by excessive oiliness. "...Sulfur with benzoyl peroxide produces a greater keratolytic effect than either substance alone."[1] The exfoliative properties of sulfur can help benzoyl peroxide to penetrate deeper into sebaceous follicles.

Two Strengths:
Sulfoxyl® Lotion Regular (5% benzoyl peroxide and 2% sulfur) and Sulfoxyl® Lotion Strong (10% benzoyl peroxide and 5% sulfur) in a grease-free washable base.

Benoxyl® Lotion

A good way to start benzoyl peroxide therapy. Benzoyl peroxide alone has been described as "a triple action drug: (1) it suppresses *C. acnes* in vivo; (2) it is comedolytic and (3) it is a counter-irritant."[3]

Two Strengths
Benoxyl® 5 Lotion (5% benzoyl peroxide) and Benoxyl® 10 Lotion (10% benzoyl peroxide) in a grease-free washable base.

PanOxyl® Gel

"The most potent forms of benzoyl peroxide are the new alcohol gels such as PanOxyl. Once the gel is applied to the skin, the solvent evaporates and deposits a concentrated form of depot free-radical oxygen which...is capable of penetrating into the sebaceous follicles and suppressing the *C. acnes*. This topical agent is much more effective in suppressing the fatty acids and the bacterial counts than systemic tetracycline and also produces a more rapid clinical improvement... No new lesions usually appear after 3 weeks and after 2 months the patient is usually free of the acne problem."[2]

Two Strengths:
PanOxyl® 5 Gel (5% benzoyl peroxide) and PanOxyl® 10 Gel (10% benzoyl peroxide) in an alcohol gel base.

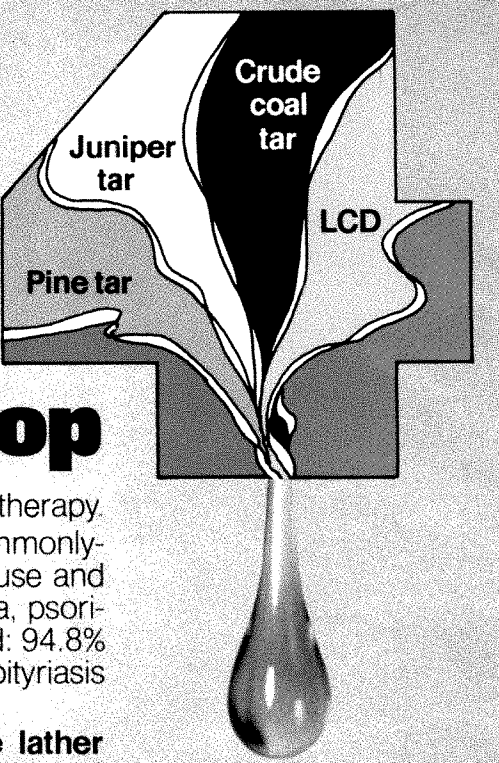
Tars have an important place in the management of seborrhea and psoriasis, but there is no clear cut agreement on when to use which.
A prudent approach:



Four tars in every golden drop

Now, a spectrum of tars maximizes the benefits of tar therapy. Polytar® Shampoo combines four of the most commonly-prescribed tars in one formula that is pleasant to use and therapeutically effective against dandruff, seborrhea, psoriasis and pityriasis capitis. Excellent results reported: 94.8% "very good" and 5.2% "good" in one study of both pityriasis capitis and psoriasis.*

And patients are pleased with the pure white lather that is as esthetically pleasing as a fine cosmetic and leaves hair lustrous and manageable.

*Bastos, A. O Medico, Vol. LXVI: 758-762, 1973

Books

Malignant Melanoma: Clinical and Histological Diagnosis, by Vincent J. McGovern, MD, 178 pp, 121 illus, $22.50, John Wiley & Sons, Inc, 1976.

Melanoma is one of the oversubscribed subjects. Perhaps more is written about this cutaneous tumor in a year than on any other comparable topic in dermatology. Now, Vincent McGovern, a long-standing giant in the field, offers a slim, slick volume about melanoma that is neatly divided into 12 short essays, commencing with "Pigmented Nevi" and concluding with "Problems." The book is a good deal thinner than the listed pages, because in addition to pictures and text there are very wide margins and numerous blank pages, presumably for notes. In addition, while many of the pictures are of good quality and well printed, others are not, and there are no color prints of clinical lesions. Even more appalling is the hasty and unevenly written text which at times is downright awkward. Basically it reflects Dr McGovern's own personal experiences and his assessment of the literature before 1974. Since the melanoma field is rapidly evolving, the book will offer little to experts in the field because it does not consider or evaluate the newer information developed subsequent to 1974. Also most of the information has been published elsewhere and is fairly common knowledge, so that informed residents will gain nothing from an encounter with this book. Perhaps the only persons to benefit would be young medical students becoming interested in the field of melanoma for the first time and advanced nursing students. I predict this period piece will languish on medical school library shelves as a historical contribution. As of 1977 it is virtually out of date.

WILLIAM L. EPSTEIN, MD
San Francisco

Biomedical Aspects of Human Wart Virus Infection (Proceedings of a Fondation Mérieux Seminar held in Lyon, France, Dec 15-16, 1975), edited by Michel Prunieras, 286 pp, with illus, Fondation Mérieux, 1976.

A famous Indian medicine man once stated categorically that "I don't fool around with no warts. There's more serious diseases to be worked on than warts." While many dermatologists heartily concur, virologists, molecular biologists, and cancer experts are looking at the wart virus as a potential probe to investigate transformation of human epidermal cells into benign hyperplasias called warts and into potentially malignant lesions of epidermodysplasia verruciformis. Because of this interest a small group of wartologists met in cold, dank Lyon in December 1975, where they were immeasurably warmed by the gracious hospitality, excellent food, and very stimulating and often speculative discussions. Fortunately the deliberations of the august group were recorded in a large paperback book edited by Michel Prunieras and available gratis on a first come, first served basis by writing to Dr Renee Triau in care of the Institut Merieux, 17, Rue Bourgelat, Lyon, France 69002.

The book is divided into three sections. The first consists of six papers concerned with in vivo and in vitro studies of the biologic behavior of papilloma viruses. The second part deals with the clinical appearance, especially of epidermodysplasia verruciformis, and a number of light and electron microscopic autoradiographic studies of these viral tumors in man. The final section consists of 15 papers on the immunology of human warts and overall is an excellent review of the subject. Although the book is printed on soft paper, there are innumerable large illustrations, many of which are of excellent quality, that clearly make the point that patients with epidermodysplasia verruciformis virtually look alike. It should be cautioned that because none of these papers were refereed, a degree of speculation creeps into many of the articles so that a wary reader will do well to keep a pinch of salt handy. However, the book is very easy reading, partially because it is printed in large, bold type, mostly in English, and it accurately portrays the state of the art at the present time. Unfortunately, the stimulating papers by Crossant and Orth presented at the seminar were not included in the final publication. Their important new studies with wart virus hybrids have been left out. The interested reader is referred to the later issues of the *Comptes Rendus Hebdomadaires des Seances de l'Academie des Sciences* where these authors are want to publish their findings. The sum—any freeloader who is interested in warts will be well served to spend a few pennies to write for this interesting and often intriguing volume.

WILLIAM L. EPSTEIN, MD

Selections From the Transactions of the Dermatological Society of Greater New York, excerpted and annotated by Henry Silver, MD, and Morris Leider, MD, assisted by Andrew G. Franks, MD, 587 pp, privately published, 1976.

This is an extraordinary publication—in numerous ways a unique one.

If you want to learn and read about recent theories of pathogenesis and find new laboratory procedures, do not look for them in this volume. But if you are as interested as every American dermatologist should be in the evidences of the day-by-day accre-

tion of clinical dermatologic knowledge, reading the fascinating presentations in this volume will bring you rich rewards.

There are also invaluable facts and findings brought to light in the 50 years of proceedings and the hundreds of case presentations and their discussions by the members of this relatively small, private, unendowed New York dermatological society. And in the progression of years, you will find documented the development of dermatology and syphilology during half a century covering one of the most critical and revolutionary periods of medicine. The gamut of diagnoses of rare and instructive cases and the profuse commentaries display the mutation of our specialty from a masterly, morphologically oriented discipline to a leading biological science that exercises profound influences on all clinical medicine.

But some of the most fascinating features of this book will be found between the lines. For example, you will find in these pages clear evidence of the melting pot of American medicine and proof of how much was contributed to medicine in the United States by the diversity of knowledge, background, training and philosophies of colleagues who emigrated from abroad. You will be sad to note in the sequential years of the discussions the demise of old tenets and approaches, devoutly held and fondly followed; and you will be astonished and pleased by the prescience and "modern" thinking—by the ideas and concepts—forcefully expressed so many years ago. Among these are numerous ideas and concepts that are being advanced as new today.

Perhaps the most impressive and remarkable of all is this volume's proof of how much can be accomplished by the dedication and ability of a small, heterogeneous group of physicians, held together, guided and inspired by a selfless and indefatigable leader, Dr Henry Silver, who founded the society in 1924 and has been its executive secretary and treasurer ever since. Every page of these annotated and edited transactions bears the stamp of Dr Silver's unflagging devotion, plus the etymological dexterity of Dr Morris Leider and the patient precision of Dr Andrew Franks.

I do not know where or how you can obtain this privately published book. But if you have an ounce of historical interest in dermatology, write and ask Dr Silver at 1 W 85th St, New York, NY 10024.

MARION B. SULZBERGER, MD
San Francisco

Seventh International Conference on Sarcoidosis and Other Granulomatous Disorders, edited by Louis E. Siltzbach, 751 pp, with illus, $53, New York Academy of Sciences, 1976.

Every year members of the New York Academy of Sciences are rewarded by being allowed to select gratis a number of volumes of the Annals of the New York Academy of Sciences. These volumes always include a wide range of interesting topics presented in the form of conferences or as monographs, and every member thus comes away satisfied with his or her selections. Unfortunately most of these volumes are never consulted again except for very special reasons. Since the center of medical interest has shifted westward from the New York environs, many young physicians are completely unaware of the Annals, and the data contained in these volumes often slips into the backwater of medical information.

As there are so many publications of the Annals, these are seldom if ever reviewed in the ARCHIVES, but it seemed appropriate to consider volume 278, *Seventh International Conference on Sarcoidosis and Other Granulomatous Disorders.* This 750-page volume is crammed with 83 reports, which cover all aspects of sarcoidosis including epidemiology, clinical, immunology, etiologic suggestions, and animal models, as well as therapy. The sections on other granulomas unfortunately cover a very small spectrum and concentrate for the most part on Crohn disease. Despite the unevenness of the reports and the fact the volume is published on inferior paper, which makes the photomicrographs and electron micrographs virtually useless, this book should be read by all scholars of sarcoidosis and granulomas and by others interested in learning the state of the art of this intriguing subject.

News and Notes

Fellowship in Bangkok, Thailand.—Anyone who is interested in a fellowship at the Institute of Dermatology, Bangkok, Thailand, may write to Dr Renoo Kotrajaras, Institute of Dermatology, 420/7 Rajavithi Rd, Bangkok 4.

Faculty Position.—The Department of Dermatology, University of California at San Francisco School of Medicine, is searching for a young dermatologist to set up a full-time research unit at San Francisco General Hospital. Candidates should be board eligible or board certified dermatologists who have had at least two years of basic science training and who would be willing to spend up to 75% of their time in the laboratory. Individuals with a chemistry background and who have worked with mediators of inflammation are encouraged to apply. The position being offered is for assistant professor, and the salary is negotiable. The University of California is an equal opportunity employer with an affirmative-action faculty recruitment program. Please send resumés or inquiries for further information to William L. Epstein, MD, chairman, Department of Dermatology, A-342, University of California, San Francisco, CA 94143.

American Board of Dermatology Examinations.—The next examinations of the American Board of Dermatology will be held on Nov 12, 13, and 14, 1977, in Chicago, at the Holiday Inn, O'Hare/Kennedy Convention Complex. The written and practical examinations will be given during a three-day period with all candidates taking both parts. All physicians who complete the required training by June 30, 1977, are eligible to apply to take the 1977 examinations. Applications must be received by the Board office by not later than June 1, 1977. Clarence S. Livingood, MD, Executive Director.

Annual Meeting.—The annual meeting of the Society for Investigative Dermatology, Inc, will be held at the Sheraton Park Hotel in Washington, DC, April 28 to 30, 1977.

Atlantic Dermatological Conference.—The next meeting of the Atlantic Dermatological Conference will be held at the Waldorf-Astoria Hotel, New York City, Friday and Saturday, May 6 and 7, 1977. Address all inquiries to Peter Lombardo, MD, 120 E 64th St, New York, NY 10021.

International Symposium.—An international symposium on dermatopathology entitled "Histological Differential Diagnosis of Skin Diseases," organized by the Department of Dermatology of the University of Munich, Germany, and the Departments of Dermatology and Pathology of New York University School of Medicine will be held in Munich, Germany, on Friday, Saturday, and Sunday, June 16 through 18, 1978. The chairman will be Otto Braun Falco, University of Munich and A. Bernard Ackerman, New York University School of Medicine. The symposium will be conducted in English, will have an international faculty, and will focus on 45 difficult problems in histologic differential diagnosis of cutaneous diseases. Special emphasis will be given to histologic patterns that are diagnostically distinctive of inflammatory skin diseases and to current concepts of cutaneous and systemic malignant lymphomas.

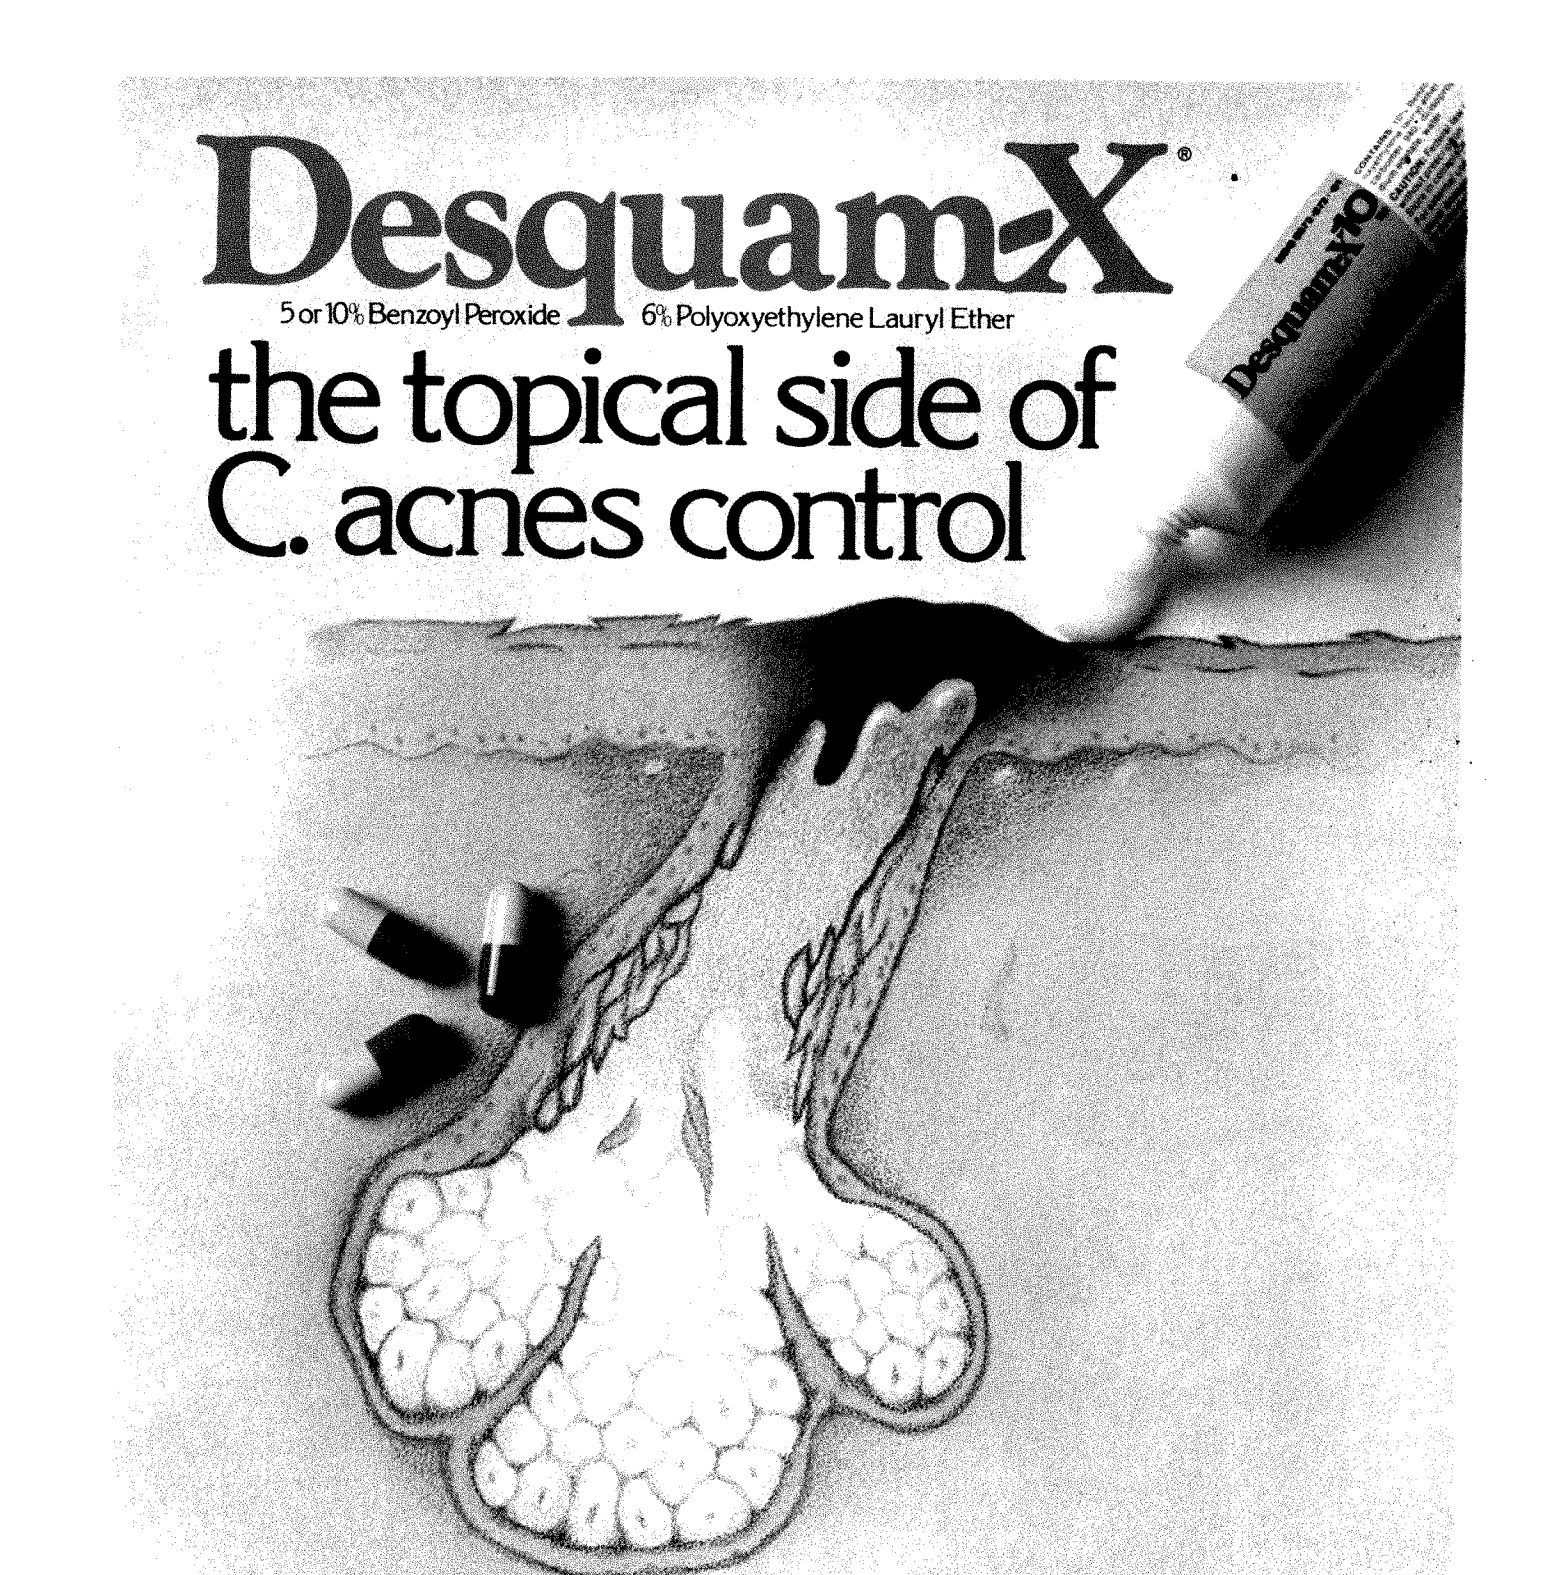
A special group flight at considerable savings for registrants in the symposium has been arranged. For additional information write to A. Bernard Ackerman, MD, Dermatopathology Section, New York University Medical Center, 562 First Ave, New York, NY 10016, or Helmut H. Wolff, MD, Dermatologische Klinik, Frauenlobstrasse 9, 8000 Munchen, West Germany.

Pacific Dermatologic Association Essay Contest.—The 29th annual meeting of the Pacific Dermatologic Association will be held in Portland, Ore, July 24-28, 1977. Each year the Pacific Dermatologic Association encourages young dermatologists to submit essays on original work. The Nelson Paul Anderson Memorial Essay Contest is open to all physicians who are in graduate dermatologic training or who are not more than five years from completing such training. Essays may be submitted by doctors residing in the geographical area of the Pacific Dermatologic Association, ie, the western United States (California, Oregon, Alaska, Nevada, Washington, Idaho, Utah, Arizona, Hawaii, Montana, Wyoming, Colorado, New Mexico), British Columbia and Alberta, Canada, Mexico, Australia, New Zealand, Japan, and the Philippines. The winning essayist will receive a cash prize of $500 and his expenses will be paid to the next annual meeting. Essays will be judged on the following considerations: (1) originality of idea, (2) potential importance of work, (3) evaluation of results, (4) experimental methods and use of control, and (5) clarity of presentations. Six copies of the essay shall be submitted under a nom de plume, with no information in the paper that will lead to recognition by the judges of the institution or clinic where the work was done. The essay with nom de plume shall be accompanied by a plain, sealed envelope enclosing the name and address and nom de plume of the author. Entries must be received by the secretary, Jack E. McCleary, MD, 4955 Van Nuys Blvd, Sherman Oaks, CA 91403, no later than June 1, 1977.

Desquam-X®

5 or 10% Benzoyl Peroxide 6% Polyoxyethylene Lauryl Ether

the topical side of C. acnes control



Desquam-X5®

Desquam-X10®

CONTENTS: Desquam-X 5 contains 5% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

Desquam-X 10 contains 10% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

INDICATION: A topical aid for the control of acne vulgaris.

ACTION: Provides the desirable drying and desquamation needed in the topical treatment of acne. Desquam-X has been demonstrated to have anti-bacterial effects, especially against Corynebacterium acnes.

DIRECTION FOR USE: After washing as instructed, rub Desquam-X into affected areas twice daily. In fair-skinned individuals or under excessively dry atmospheric conditions it is suggested that therapy be initiated with one application daily. The desired degree of drying and peeling can be obtained by modification of the dosage schedule.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Desquam-X.

PRECAUTIONS: Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medication out of the reach of children.

NOTE: May bleach colored fabrics.

HOW SUPPLIED: Plastic tubes 1.5 oz. (42.5 gm.)

CAUTION: Federal law prohibits dispensing without prescription.

Dermatoses

rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

CLINICAL APPOINTMENTS

PHARMACEUTICAL RESEARCH

Selected client companies, long respected for leadership in medical research, offer attractive appointments to their clinical staffs. Candidates should have credentials from a first line medical school, with a background in internal medicine, pediatrics, dermatology, clinical pharmacology, anaesthesiology, cardiology or similar specialty area. Board or Board eligibility will be a distinct asset. Experience in industry will also be valuable, though not necessary. A serious interest in the design and assessment of clinical studies is, however, essential.

We believe, these appointments, together with their excellent fringe benefits, regularity of hours and association with professional associates working at the forefront of medical research offer an attractive, meaningful alternative for the physician.

Your curriculum vitae or similar particulars will re-

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform-® Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone
(iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

Consult complete product literature before prescribing.

CIBA

ok closely at these patients. heir dermatologist had them on a KOMEX®/KOMED® regimen.

Step 1 KOMEX®

"...toward keeping the skin meticulously clean...to decrease the usually concomitant oiliness."[1]

Cleanses thoroughly yet gently.

The detergent cleansing effect of Komex acne cleanser is uniquely enhanced with mild dissolving sodium borate particles (Scrubules) for effective yet gentle cleansing of the skin. Komex removes surface debris. Clears comedones. Cleans clogged pores. Unplugs hair follicles. And removes oils.

Mild abradancy won't damage skin.

"A frequently overlooked source of excessive friction is the practice of vigorous scrubbing in an attempt to wash acne away. The use of brushes and other scrubbing techniques can induce significant inflammatory lesions...Elimination of sources of excessive friction lead to rapid improvement[2]

The patented Komex Scrubules enable doctor and patient to control particle dissolution from 0-60 seconds, depending on water dilution. Acne patients can't overabrade with Komex. A significant exclusive.

Conditions the skin.

In fact, the skin *conditioning* effect of Komex acne soap is truly phenomenal. You can detect some of it in the patient photos. But it really must be seen – and felt.

Step 2 KOMED®

"...to peeling of the skin so that the follicular orifices are kept open."[1]

Employs a non-comedogenic form of sulfur.

Komed Lotion works beautifully with Komex.
"The sovereign remedy in the topical management of acne vulgaris is sulfur."[3]
"Sulfur...still the most effective remedy...In addition ...salicylic acid and other peeling chemicals are used in cosmetically elegant lotions..."[4]
The exclusive Komed formulation keeps skin dry and desquamating with salicylic acid and *non-comedogenic* sodium thiosulfate.

"Suspensions and creams containing elemental sulphur were shown to be capable of inducing comedones in the rabbit ear and on human backs."[5]

Has "excellent patient appeal."

"All of the patients liked the fact that (Komed) dries quickly to an invisible film...the female patients found that the lotion did not interfere with the use of non-oily cosmetics. Male patients also appreciated the lack of a masking effect, the absence of staining properties, and the fact that the lotions blend with natural skin tone."[6]

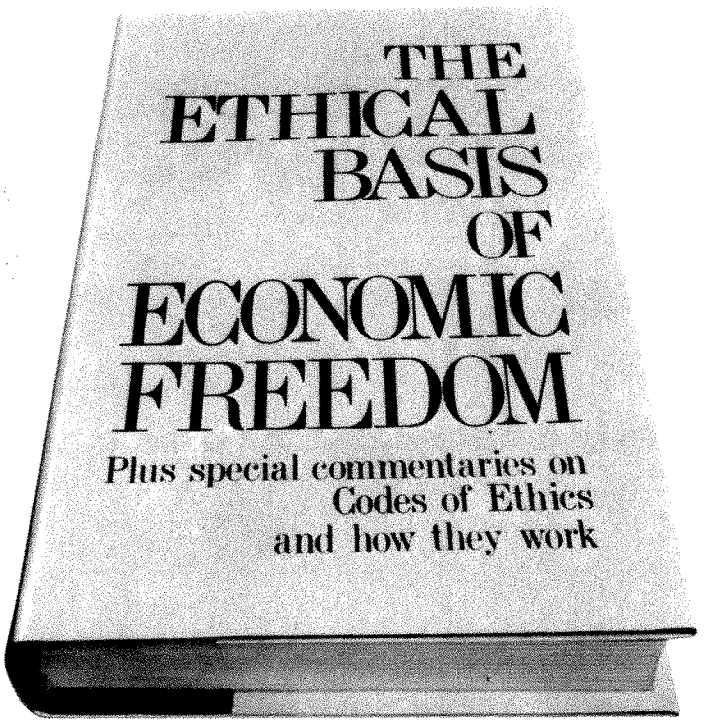
6. Sewell JW Jr: Therapeutic and cosmetic advantages of a nonpigmented acne lotion. Cutis

What are Leon Jaworski, Treasury Secretary William Simon and the president of the American Medical Association all doing in one book?



They have joined with eminent economists, anthropologists, lawyers, association executives and other experts to discuss the headline issue of today—everyday ethics—America's urgent problem

Authors on ethics include Leon Jaworski, the celebrated lawyer, Dr. Max Parrott, president of the American Medical Association, the articulate Treasury Secretary William E. Simon, anthropologists Dr. Roy Rappaport and Dr. James Peacock, economic historians Dr. Wolfram Fischer and Dr. John B. Condliffe. Dr. Jack Behrman writes on transnational corporate practices, Earl Kintner on regulatory law, Kenneth Fiester on labor ethics. Andrew Kneier discusses conflicts of interest in government. Clifford Graese, partner in the world's largest accounting firm, presents new concepts in accounting ethics.

THE ESSAYS ON ETHICS present the problem in perspective and draw a clear relationship between ethics and the viability of our free enterprise system.

THE COMMENTARIES ON CODES OF ETHICS begin with an introduction by Arch N. Booth, past president of the Chamber of Commerce of the U. S., and continue with analyses of complete codes of ethics by executive officers of national trade and professional associations, with emphasis on how to make such codes more effective.

If your bookstore does not have "The Ethical Basis of Economic Freedom," please order direct from American Viewpoint, Inc. 448 pages in attractive hard cover, $12.50 postpaid.

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

SQUIBB® The Priceless Ingredient of every product is the honor and integrity of its maker.™

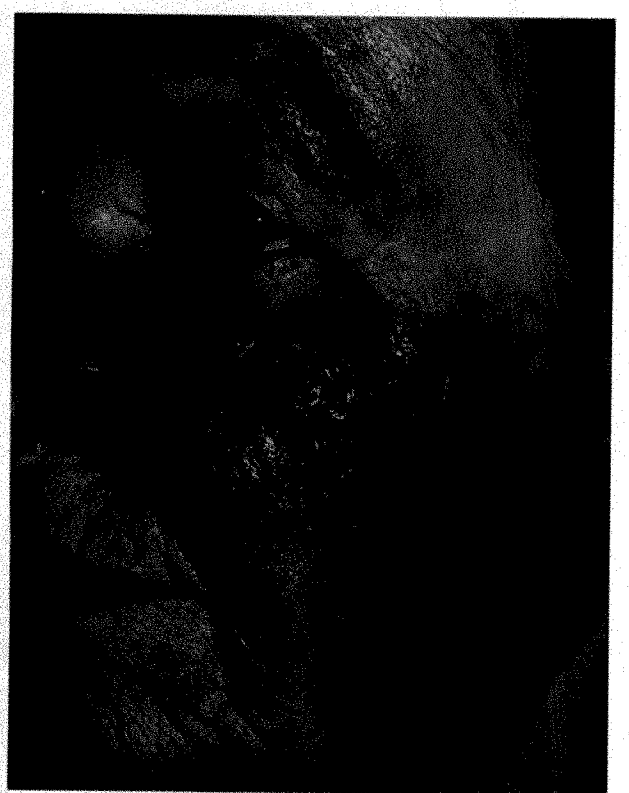
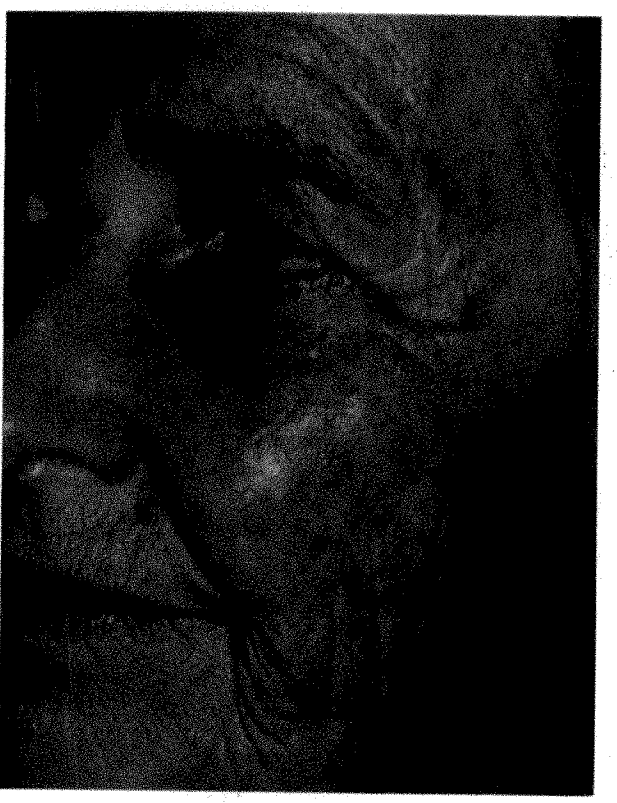
"Major improvement" in 5 days



Contact Dermatitis

Condition due to excessive use of 5-FU. Patient presented with intense pruritus, severe pain. Facial involvement sharply demarcated and acutely eczematous, erythematous and swollen – extending up into infra-orbital regions, but sparing eyelids and eyebrows.



After 5 days

Halog 0.1% cream applied twice daily. Pruritus and pain relieved within 48 hours. Examination on day 5 of therapy revealed major improvement with only mild, residual erythema still present. Total resolution of all lesions nine days later, at which time therapy was discontinued.

Case history on file at Squibb Institute for Medical Research.

A NEW PRESCRIPTION TO ASSURE YOUR TRAVELING PATIENTS A BON VOYAGE.

Physician's Guide to Medical Advice for Overseas Travelers

Jet lag fatigue, Montezuma's Revenge, airport coronaries--they've become all too common words in the medical vocabulary as increasingly larger numbers of people avail themselves of the speed and ease of jet travel for overseas vacation and business trips. And, in the process, they expose themselves to health risks rarely encountered at home.

Physician's Guide to Medical Advice for Overseas Travelers was developed by the AMA to help practicing physicians render preventive medical services to traveling patients.

It provides a wealth of information, such as how to protect patients against tropical diseases, time zone changes, parasites, tuberculosis and complications of existing handicaps. What to advise about diets and personal hygiene in the tropics, overseas medical care, immunizations.

Order your copy today. The price is only 60¢. Write: ORDER DEPT., at the address below, and specify pamphlet OP-411. Enclose check.

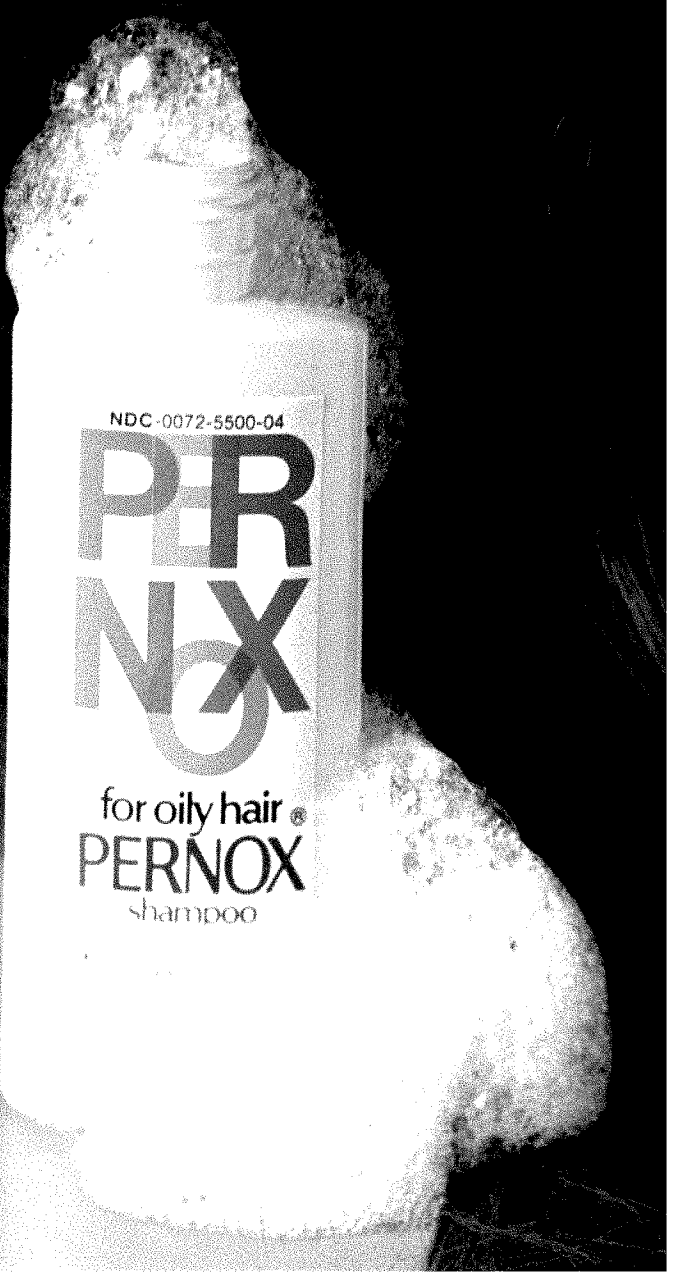
CONTEMPORARY AND EFFECTIVE

For seborrhea oleosa and the oily hair and scalp associated with acne



- Thorough cleansing of oily hair and scalp.
- Leaves patients' hair soft, manageable, fresh smelling.
- Elegant herbal scented shampoo.
- A special formulation designed to cleanse and condition oily hair.
- Its pH of 5.5 is gentle to the scalp.
- Can be used as often as necessary, preferably every day, to keep hair looking fresh and healthy.
- CONTAINS NO FORMALDEHYDE.

Supplied: 4 oz. and 8 oz. plastic bottles.

Pernox Shampoo® is adjunctive therapy especially formulated for oily scalps associated with acne.

Cordran® (Flurandrenolide)

Description: Cordran* (flurandrenolide, Dista) is a potent corticosteroid intended for topical use. **Actions:** Cordran is primarily effective because of its anti-inflammatory, antipruritic, and vasoconstrictive actions. **Indications:** For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. **Contraindications:** Topical corticosteroids are contraindicated in vaccinia and varicella and in patients with a history of hypersensitivity to any of their components. **Precautions:** If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, an appropriate antifungal or antibacterial agent should be used. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, there is a possibility of increased systemic absorption of the corticosteroid, and suitable precautions should be taken. Although topical corticosteroids have not been reported to have an adverse effect on pregnancy, the safety of their use on pregnant women has not been absolutely established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time on pregnant patients. These products are not for ophthalmic use. **Adverse Reactions:** The following local adverse reactions have been reported with topical corticosteroid formulations: acneform eruptions, burning, dryness, folliculitis, hypertrichosis, hypopigmentation, irritation, itching. The following may occur more frequently with occlusive dressings: maceration of the skin, miliaria, secondary infection, skin atrophy, striae. **Administration and Dosage:** For moist lesions, a small quantity of the cream or lotion should be rubbed gently into the affected areas two or three times a day. For dry, scaly lesions, the ointment is applied as a thin film to affected areas two or three times daily. [111875]

SUBSCRIPTION RATES: The yearly rate of the ARCHIVES OF DERMATOLOGY is as follows: United States and US Possessions, one year, $18; two years, $28; all other countries, one year, $28; two years, $38. Special yearly price to residents, interns and medical students in the United States and US Possessions, $9.

THE ARCHIVES OF DERMATOLOGY is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

Please address communications concerning accepted or published communications to: AMA Specialty Journals, 535 N Dearborn St, Chicago, IL 60610.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 600 Third Ave, New York, NY 10016, Area Code 212-867-6640.

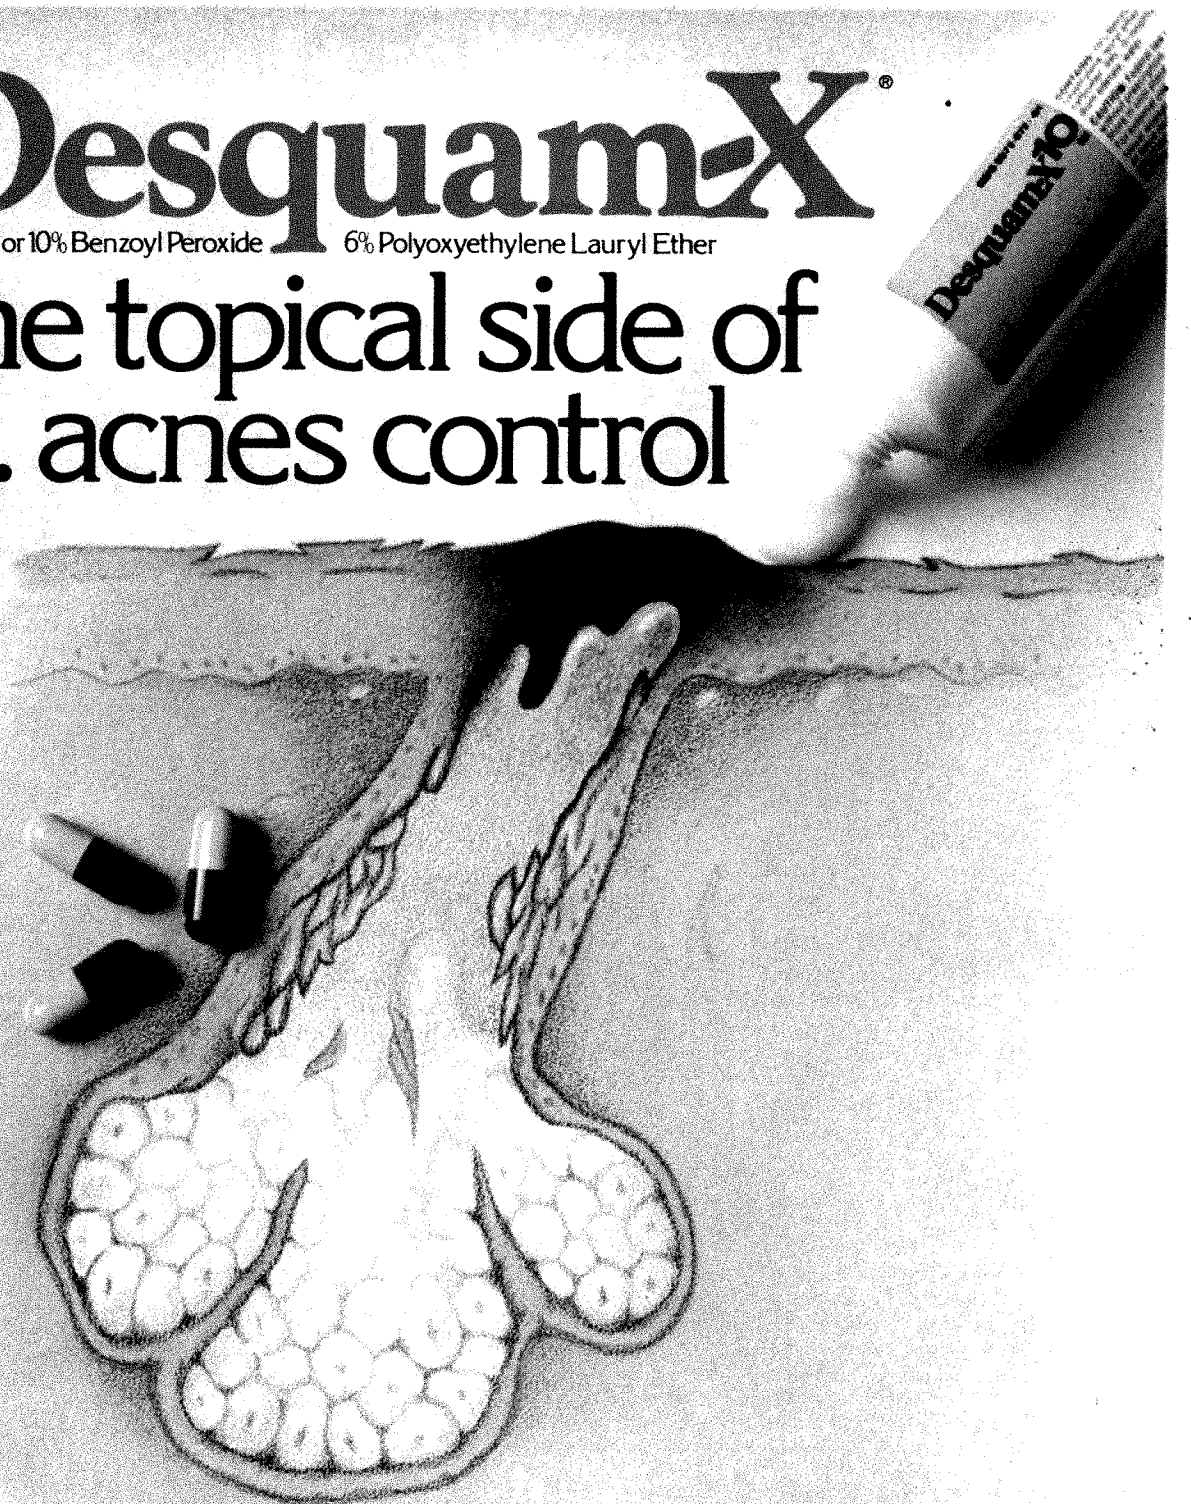
ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

Desquam-X®

5 or 10% Benzoyl Peroxide 6% Polyoxyethylene Lauryl Ether

the topical side of C. acnes control



Desquam-X5®

Desquam-X10®

CONTENTS: Desquam-X 5 contains 5% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

Desquam-X 10 contains 10% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

INDICATION: A topical aid for the control of acne vulgaris.

ACTION: Provides the desirable drying and desquamation needed in the topical treatment of acne. Desquam-X has been demonstrated to have anti-bacterial effects, especially against Corynebacterium acnes.

DIRECTION FOR USE: After washing as instructed, rub Desquam-X into affected areas twice daily. In fair-skinned individuals or under excessively dry atmospheric conditions it is suggested that therapy be initiated with one application daily. The desired degree of drying and peeling can be obtained by modification of the dosage schedule.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Desquam-X.

PRECAUTIONS: Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medication out of the reach of children.

NOTE: May bleach colored fabrics.

HOW SUPPLIED: Plastic tubes 1.5 oz. (42.5 gm.)

CAUTION: Federal law prohibits dispensing without prescription.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author, (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

When patient acceptance is half the problem.

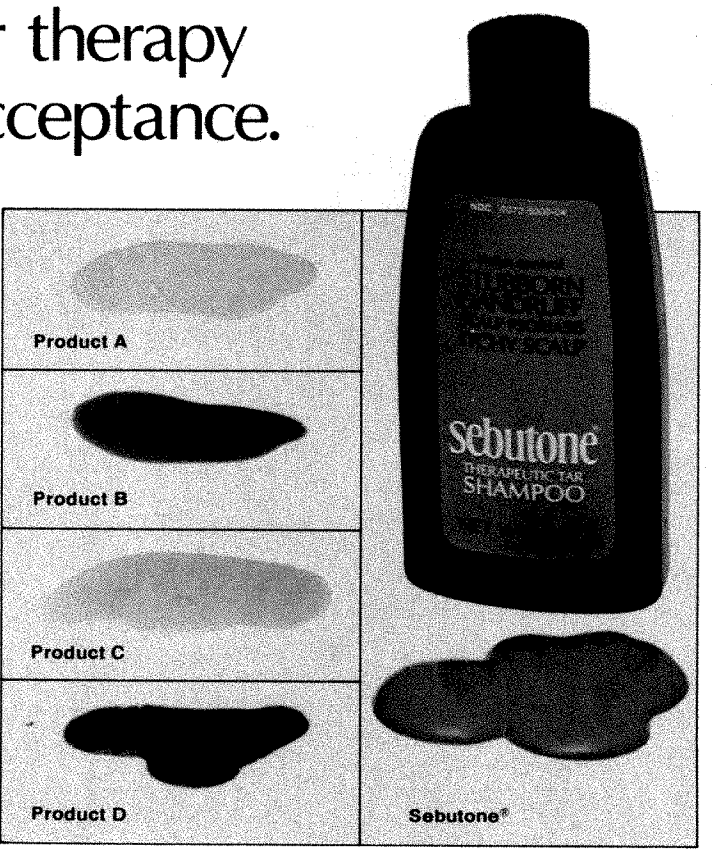
sebutone®

is the answer.

Tar is effective therapy, but it has one big drawback . . . most shampoos look like tar and, worst of all, they smell like it, too.

Sebutone® provides tar therapy with unique patient acceptance.

- Itching usually stops after the first shampoo.
- It has a clean, fresh odor patients will like.
- It is a rich, lathering shampoo with a pleasant color.
- It contains the first chemically and biologically standardized tar, developed by Westwood.
- Sebutone's tar is bioassayed to insure therapeutic activity from batch to batch.
- Available in both lotion and cream.
- In addition to 0.5% Westwood® Tar, Sebutone contains 2% sulfur and 2% salicylic acid, for increased effectiveness.
- Wood's light shows that microfine particles remain on the scalp for up to three days to provide sustained antiseborrheic action.



sebutone® Therapeutic Tar Shampoo

Substantive therapy...proven by Wood's light.

Available—Sebutone in 4 and 8 oz. bottles; Sebutone Cream in 4 oz. tubes.

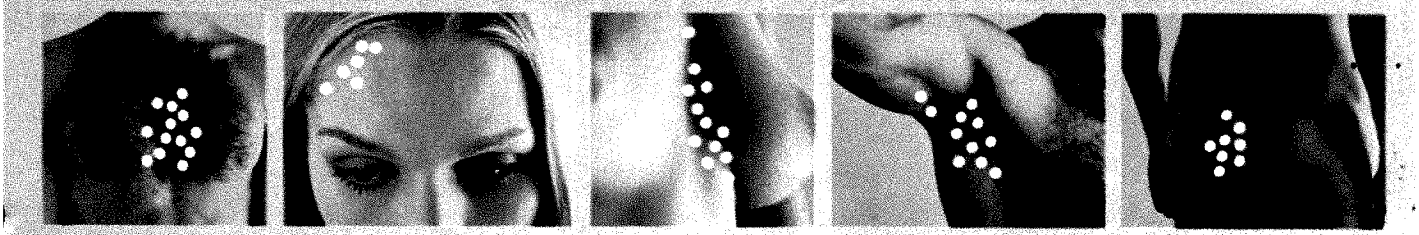
Sites of seborrhea...



Uticort™

(betamethasone benzoate)

a highly effective topical steroid in a special base

UTICORT contains the fluorinated corticosteroid ester — betamethasone benzoate 0.025% — in a specially formulated, clear, self-liquefying gel base to increase steroid activity.
Patients with seborrheic dermatitis treated with UTICORT improved 86% in an average of 11.6 days.

liquefies on application for better surface contact

UTICORT is especially valuable in the treatment of seborrheic dermatitis on hairy areas of the body.

cosmetically acceptable

UTICORT dries to a clear film and can be used confidently on either smooth or hairy skin areas. Moreover, it is greaseless, nonstaining, and nonsticky.

preservative free

Contains no parabens or other potentially sensitizing preservatives.

Brief summary of prescribing information

INDICATIONS. Uticort Gel (betamethasone benzoate) is intended for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia. Topical steroids are contraindicated in patients with a history of sensitivity to any of the components of the preparation.

This preparation is not for ophthalmic use.

PRECAUTIONS. If irritation develops, the gel should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid, and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, or in large amounts, or for prolonged periods of time.

Due to the alcohol content of the vehicle, Uticort Gel (betamethasone benzoate) may cause mild, transient stinging without irritation if used on excoriated skin.

ADVERSE REACTIONS. The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruptions, and hypopigmentation.

DOSAGE AND ADMINISTRATION. Apply to affected areas two to four times daily as needed.

HOW SUPPLIED. N 0071-3025 Uticort Gel is supplied in 15-g and 60-g tubes.

Caution: Federal law prohibits dispensing without prescription.

PARKE-DAVIS

Gets to deep fungal infections

Actual photograph of tinea unguium infection (onychomycosis).
Note typical worm-eaten appearance of fingernail destroyed by fungus.

when topicals can't.

Potent, systemic fungistat

GRISACTIN provides the antifungal activity needed to control tinea infections, including onychomycosis, that invade the dermis and deeper regions. Systemic action penetrates where topical action often fails.

GRISACTIN is effective against a wide range of fungi: *Trichophyton rubrum, T. mentagrophytes, T. tonsurans, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum canis, M. audouini, M. gypseum,* and *Epidermophyton floccosum.*

Peak serum levels are usually produced in about four hours with a single 500 mg. tablet. To meet the requirements of different patients—depending on body weight, age, severity, and location of infection—dosage is easily individualized with 125 mg. and 250 mg. capsules, and 500 mg. tablets.

Grisactin® 500

BRAND OF

griseofulvin (microsize) TABLETS

BRIEF SUMMARY
(For full prescribing information, see package circular.)

Grisactin®
Brand of
Griseofulvin (microsize)

Indications: Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum audouini, M. canis, M. gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, candidiasis (moniliasis), histoplasmosis, actinomycosis, sporotrichosis, chromoblastomycosis, coccidioidomycosis, North American blastomycosis, cryptococcosis (torulosis), *Tinea versicolor,* nocardiosis.
Contraindications: This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin.
Warnings: *Prophylactic Usage*—Safety and efficacy of griseofulvin for prophylaxis of fungal infections has not been established.
Animal Toxicology—Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in Pregnancy—The safety of this drug during pregnancy has not been established.
Animal Reproduction Studies—It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
Precautions: Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from a species of Penicillium, the possibility of cross-sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
Adverse Reactions: When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
Dosage and Administration: Accurate diagnosis of the infecting organism is essential. Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required, particularly in treatment of *tinea pedis.*
Dosage should be individualized, depending on age and severity of infection. *Adults*—0.5 Gm. daily (125 mg. q.i.d., 250 mg. b.i.d., or 500 mg./day). *Children*—10 mg./kg. daily is usually adequate (from 30 to 50 lb., 125 mg. to 250 mg. daily; over 50 lb., 250 mg. to 500 mg. daily, in divided doses).
How Supplied: GRISACTIN [griseofulvin (microsize)]—No. 442—GRISACTIN 125, each capsule contains 125 mg., in bottles of 100 and 500. No. 443—GRISACTIN 250, each capsule contains 250 mg., in bottles of 100 and 500. No. 444—GRISACTIN 500, each tablet (scored) contains 500 mg., in bottles of 60.

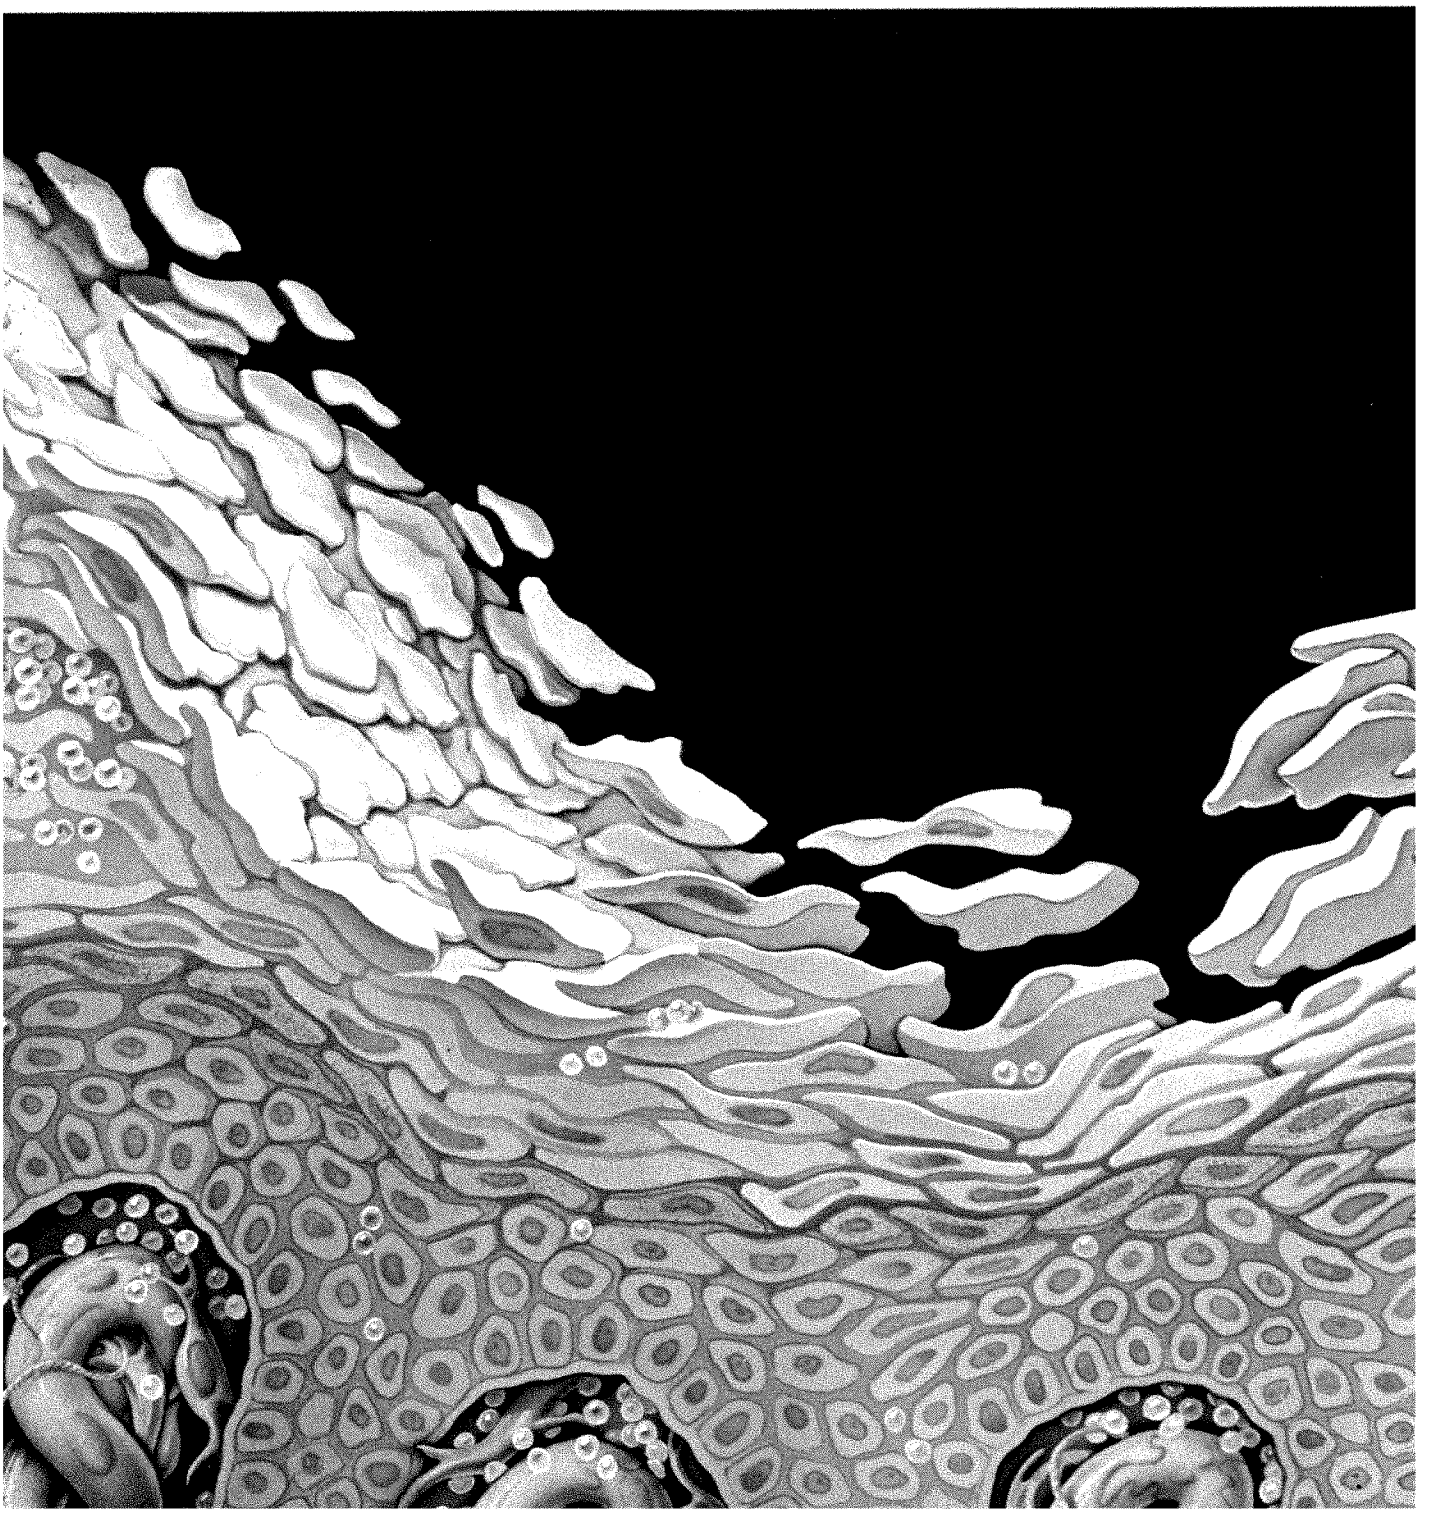
PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word ca
make an afflicted patient cringe. And,
because of the capricious, unpredictab
nature of the disease, the patient rarely
knows where or when it will recur.

Obviously, the goal is control. And,
though varied treatment modalities are
available today, none offers universal



fficacy for all patients, all of the time.

Yet, very often a highly effective topical teroid, like Lidex, (fluocinonide) can ıelp stabilize psoriasis.

Lidex. A highly effective topical steroid vith anti-inflammatory, vasoconstrictive, ntipruritic actions.

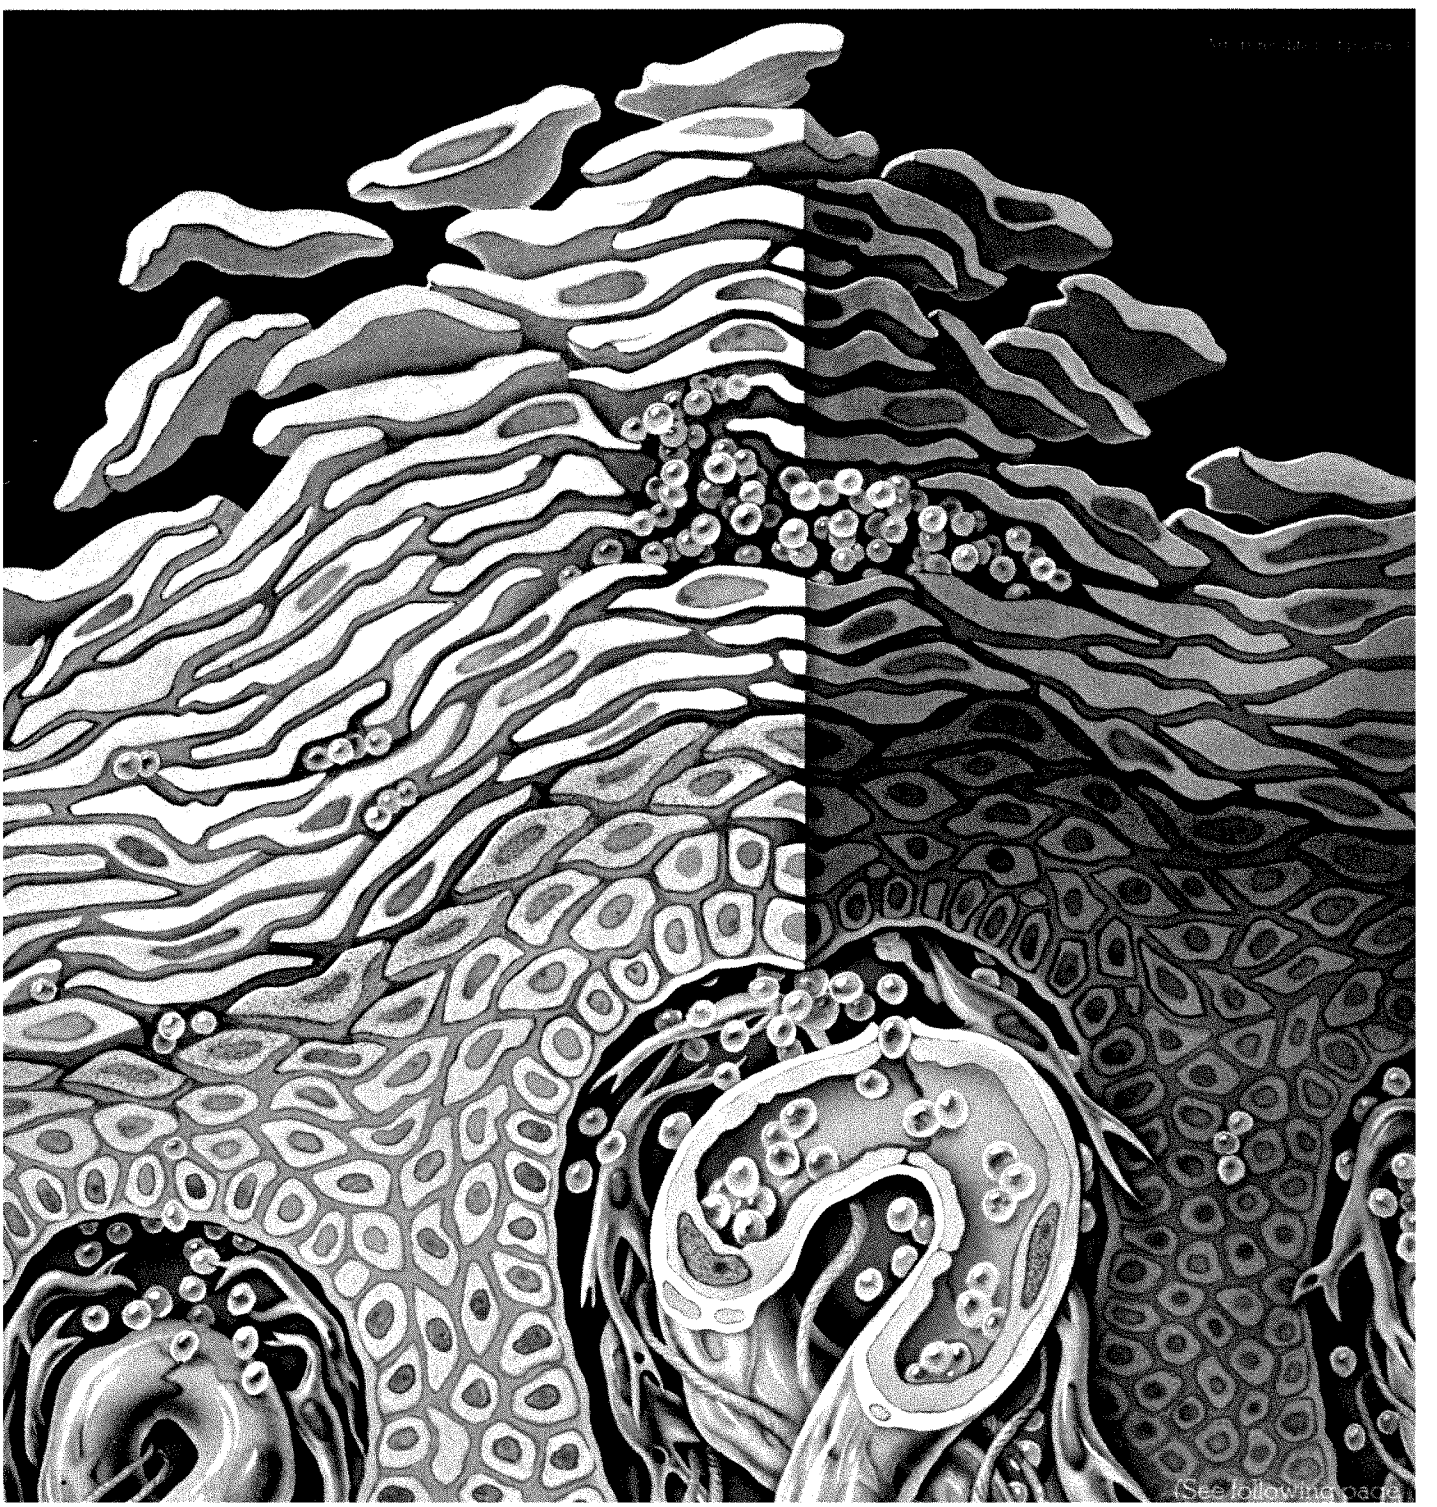
100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CALIFORNIA 94304



(See following page.)

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream – 15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment – 15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

A valuable guide to diagnostic and therapeutic procedures for the cancer patient

Current Concepts in Cancer

While national attention focuses on cancer through specialized cancer centers, physicians are aware that the majority of cancer patients are treated in office practices. For most practicing physicians, cancer treatment is not a research objective, but a very practical problem in patient management.

Current Concepts in Cancer, a compilation of articles originally published in the *Journal of the American Medical Association,* is designed to be a guide for the practitioner in the choice of diagnostic and therapeutic procedures for many types of malignancies. It presents an objective interdisciplinary view by MDs outstanding in their respective fields, emphasizing principles of diagnosis and surgical radiotherapeutic, and chemotherapeutic treatment.

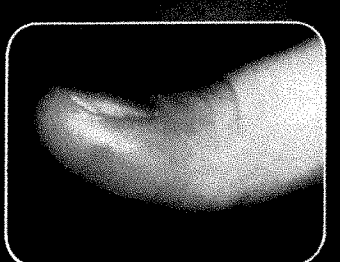
MINOCIN Minocycline HCl
Oral and Intravenous Brief Summary
Contraindications: Hypersensitivity to any tetracycline.
Warnings: Intravenous use, particularly in pregnancy, in daily doses exceeding 2 grams has been associated with deaths through liver failure. When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. This hazard is of particular importance in I.V. use in pregnant or postpartum patients with pyelonephritis. In such cases, the blood level should not exceed 15 mcgm/ml, and liver function tests should be made at frequent intervals. Do not prescribe other potentially hepatotoxic drugs concomitantly. The use of tetracyclines during tooth development (last half of pregnancy, infancy and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies to date indicate that photosensitivity is rarely reported with MINOCIN *Minocycline HCl*. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an [illegible] acidosis. CNS side effects (lightheadedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. **Newborns, infants and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg./kg. every 6 hours, demonstrated a decrease in fibula growth rate; reversible when drug was discontinued. Tetracyclines are present in the milk of lactating women who are taking a drug in this class.
Precautions: Use may result in overgrowth of nonsusceptible (cont'd)

Staph infection: Skin deeper

When the patient is penicillin-hypersensitive, when bacteriologic testing shows *Staph. aureus* to be resistant or the infection has proved unresponsive, MINOCIN *Minocycline HCl* may be an effective alternative.* Clinical studies have demonstrated satisfactory response in 156 of 173 simple or mixed skin and soft tissue infections due to staphylococci.



Actual patient photograph after 7 days of MINOCIN.

MINOCIN®
MINOCYCLINE HCl

CAPSULES 50 mg and 100 mg
SYRUP 50 mg/5 cc
INTRAVENOUS 100 mg/vial

100 or 200 mg initially, 50 mg *q.i.d.*
or 200 mg initially, 100 mg *b.i.d.*

*Tetracyclines are not the drugs of choice in the treatment of any type of staphylococcal infection. MINOCIN is indicated for treatment of *Staphylococcus aureus* skin and soft tissue infections only when bacteriologic tests indicate appropriate susceptibility to the drug.

MINOCIN Minocycline HCl
Oral and Intravenous Brief Summary (continued)
organisms, including fungi. If superinfection occurs, institute appropriate therapy. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (*e.g.*, renal, hepatic and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.
Adverse Reactions: GI: (with both oral and parenteral use): anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital region. **Skin:** maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above ("Warnings"). **Renal toxicity:** rise in BUN, dose-related (see "Warnings"). **Hypersensitivity reactions:** urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (see "Warnings"). When given in high doses, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur. **NOTE: Concomitant therapy:** Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral minocycline. Studies to date indicate that absorption of MINOCIN *Minocycline HCl* is not notably influenced by foods and dairy products.

CNS side effects including lightheadedness, dizziness, or vertigo have been reported with MINOCIN. Patients who experience these symptoms should be cautioned about driving vehicles or using hazardous machinery while on minocycline therapy.

Dermik Laboratories, Inc., Fort Washington, Pa. 19034
WHERE RESEARCH AND ECONOMY COME FIRST!

DESCRIPTION – Hydrocortisone 2½%, 1% and ½% in a water-washable cream containing purified water, propylene glycol, isopropyl myristate, cholesterol and related sterols, cetyl alcohol, sorbic acid, glyceryl monostearate, polysorbate 60, sorbitan monostearate and polyoxyl 40 stearate.

ACTIONS – Topical corticosteroids are effective primarily because of their antiinflammatory, antipruritic, and vasoconstrictive actions.

INDICATIONS – For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: In viral diseases of the skin such as varicella and vaccinia and in patients with a history of hypersensitivity to any component. Not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.

WARNING: Should not be used extensively, in large amounts, or for prolonged periods in pregnancy.

appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

ADVERSE REACTIONS – The following local adverse reactions have been reported with topical corticosteroids, either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

DOSAGE AND ADMINISTRATION – Apply to affected areas 3 or 4 times daily.

HOW SUPPLIED: Tubes – ½ oz., 1 oz.

Britain employs a predominantly nationalized free-to-user health care system. France offers its citizens a comprehensive health and social insurance system.

These highly readable, comprehensive studies, prepared by a research firm in London and published by the American Medical Association, offer an opportunity to step inside each system to examine its administration...evaluate its achievements and problems...and to get a feel for what it's like to use it and work within it.

What's more, you'll learn how and why the present systems evolved...how they are financed ...the range and quality of services available... the training and distribution of medical personnel...and what effects each system has had upon the health of the general population.

Everyone in the medical profession should read both of these fascinating studies on how other nations have organized the delivery of health care.

what's best for the care of dry, or premature aging or wrinkled skin... DUE TO EPIDERMAL DEHYDRATION?

This timely volume explores how plant and animal life has evolved to adapt to the ultraviolet "load" from the sun including the continuous repair of radiation damage. Focusing on ultraviolet photobiology, the author details the factors that might upset the delicate balance between radiation injury and repair, such as:

LIVING WITH OUR SUN'S ULTRA-VIOLET RAYS

- reduction of the ozone layer by stratospheric pollution
- natural dyes, medications, and pollutants which absorb light and pass its energy to sensitive chemicals in the cell
- the absence of radiation repair mechanisms in mutant cells.

by **Arthur C. Giese,**
Stanford University

The book reviews the nature of the sun's ultraviolet radiation as it reaches the surface of the earth today, and as it probably affected the earth in the distant past. It covers both the beneficial and harmful effects of such radiation on all life—unicellular organisms as well as multicellular plants and animals. Since the effects of the rays on an organism are primarily a result of their action upon cells, and interactions between cells, the major emphasis is on cellular response to the sun's ultraviolet radiation. Specific problems of pollution and skin damage, particularly sunburn, premature aging, and cancer induction, are discussed in detail.

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform-® Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone (iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo.
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

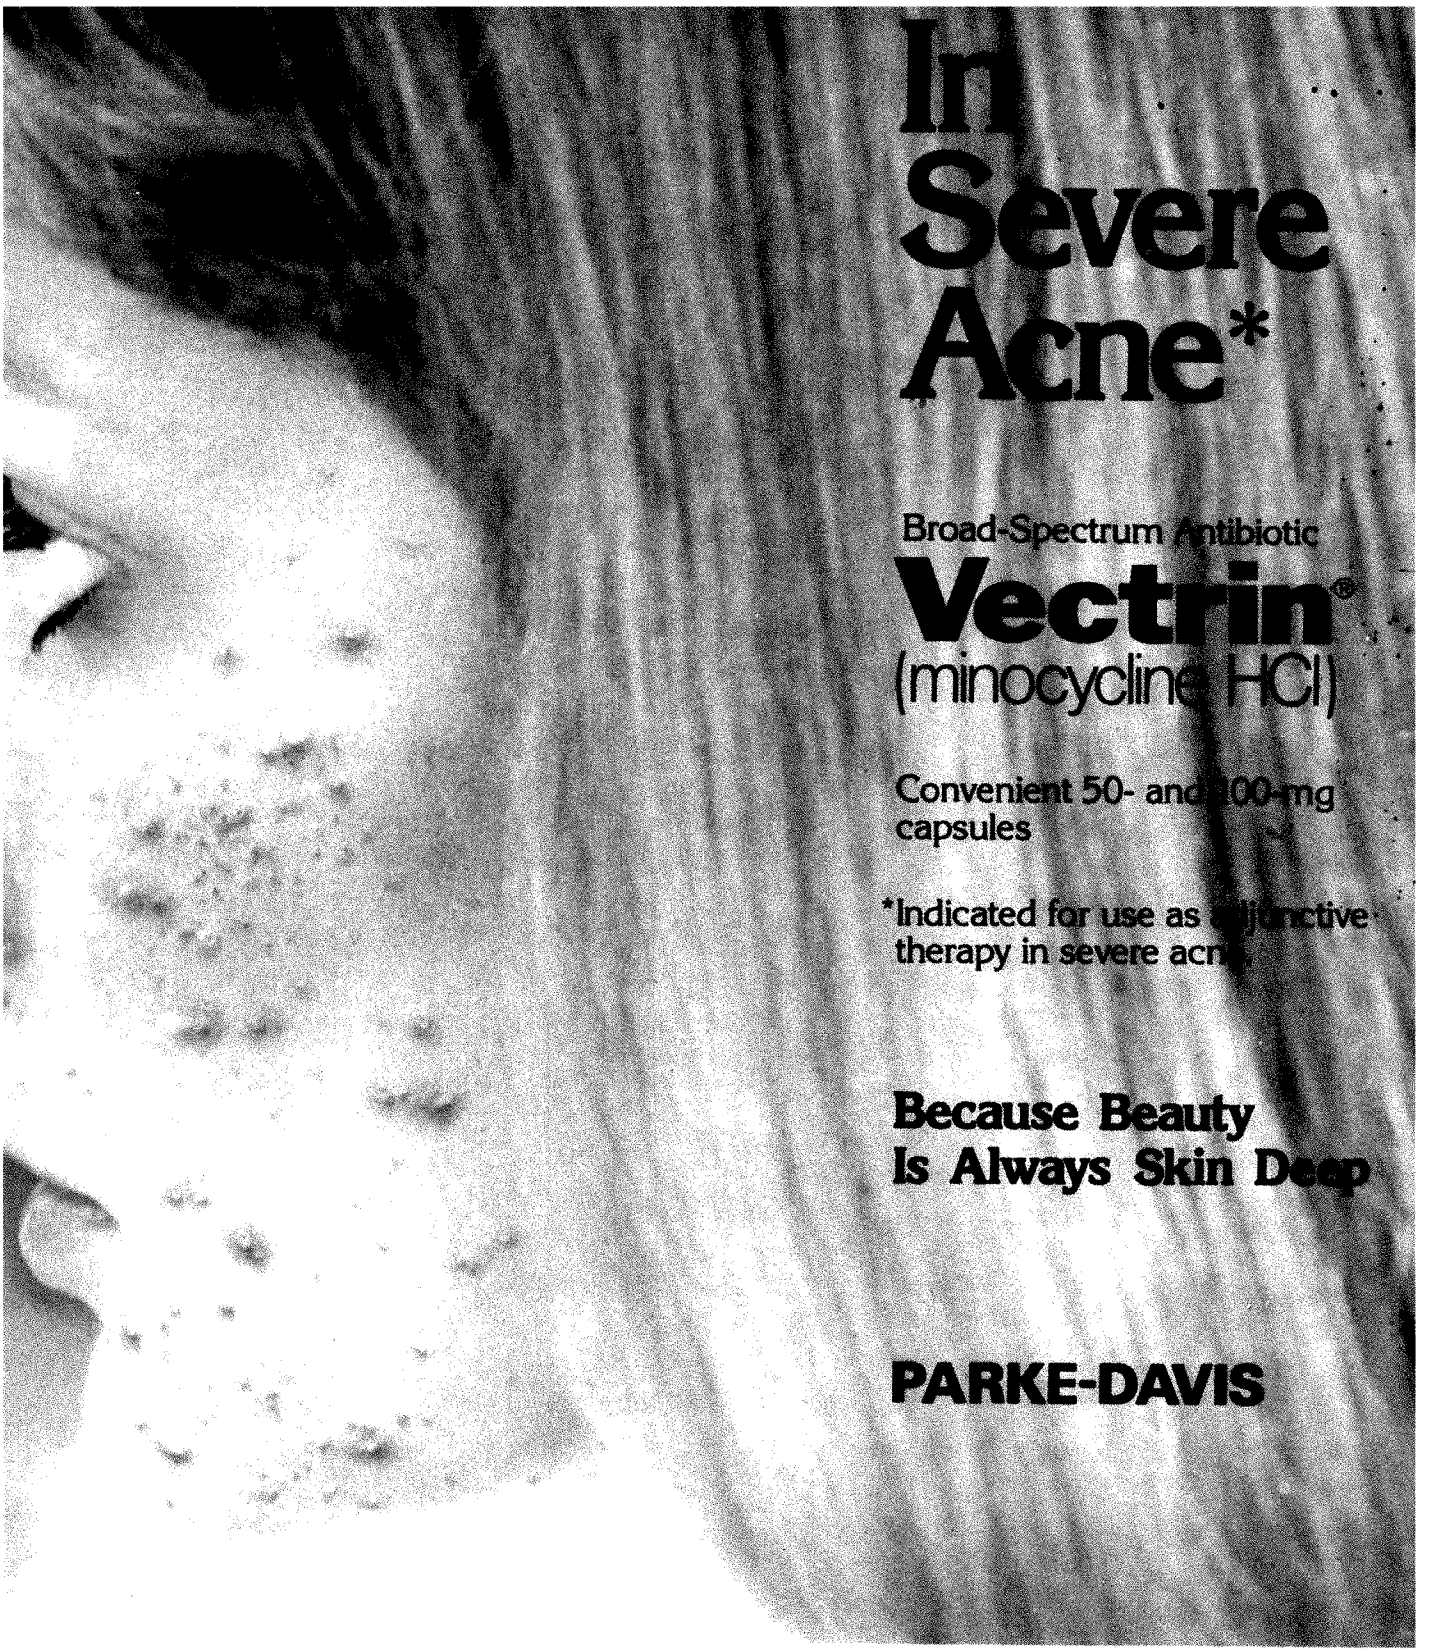
Acne illustrated by artist.

VECTRIN Capsules, 100 mg
(minocycline HCl capsules, USP)
Brief Summary of Prescribing Information

Indicated in severe acne as adjunctive therapy. Consult package insert for complete prescribing information.

Contraindication: Hypersensitivity to any tetracycline.

Warnings: When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. The use of tetracyclines during tooth development (last half of pregnancy, infancy, and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies with minocycline HCl indicated that photosensitivity did not occur. However, reports have been received. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an increase in BUN leading to azotemia, hyperphosphatemia, and acidosis. **CNS side effects:** (light-headedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. The safety of minocycline HCl for use during pregnancy has not been established. **Newborns, infants, and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg/kg every six hours, demonstrated a decrease in fibula growth rate reversible when drug was discontinued. Tetracyclines



In Severe Acne*

Broad-Spectrum Antibiotic

Vectrin®

(minocycline HCl)

Convenient 50- and 100-mg capsules

*Indicated for use as adjunctive therapy in severe acne.

Because Beauty Is Always Skin Deep

PARKE-DAVIS

are present in the milk of lactating women who are taking a drug in this class.

Precautions: Use may result in overgrowth of non-susceptible organisms, including fungi. If superinfection occurs, antibiotics should be discontinued and appropriate therapy instituted. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (eg, renal, hepatic, and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.

Adverse Reactions: GI: Anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital region. **Skin:** Maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above. (See Warnings.) **Renal toxicity:** Rise in BUN, dose-related. (See Warnings.) **Hypersensitivity reactions:** Urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** Hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (See Warnings.) When given over prolonged periods, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur.

NOTE: Concomitant therapy: Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral tetracycline. Studies to date indicate that absorption of VECTRIN (minocycline hydrochloride) is not notably influenced by foods and dairy products.

½
Therapeutic effectiveness with half the dose

Schering

Once-a-day dosage

NEW Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

***"P/G" means a new polyethylene glycol system for enhanced absorption –**

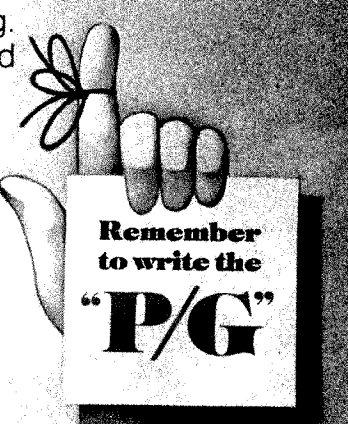
A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**



**Based on list-price comparison.

See Clinical Considerations section on following page.

Schering

NEW P/G Fulvicin P/G

griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

Clinical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated for the treatment of ringworm infections of the skin, hair, and nails, namely, tinea corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea unguium (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum,* and *Epidermophyton floccosum.* Note: Prior to therapy, the type of fungi responsible for the infection should be identified. The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone. Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. **CONTRAINDICATIONS** This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin. **WARNINGS** *Prophylactic Usage.* Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established. *Animal Toxicology.* Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin once a week during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard. In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals. *Usage in Pregnancy.* The safety of this drug during pregnancy has not been established. *Animal Reproduction Studies.* It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats but investigation in man failed to confirm this. **PRECAUTIONS** Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done. Since griseofulvin is derived from species of penicillin, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty. Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated. Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy. Barbiturates usually depress griseofulvin activity, and concomitant administration may require a dosage adjustment of the antifungal agent. **ADVERSE REACTIONS** When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities. Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs. When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

Sulfoxyl® Lotion Regular ℞
Sulfoxyl® Lotion Strong

Composition: Sulfoxyl Lotion Regular contains 5% benzoyl peroxide and 2% sulfur; Sulfoxyl Lotion Strong contains 10% benzoyl peroxide and 5% sulfur, each in a lotion base formulated with polyethylene glycol monostearate, stearic acid, glycerol monostearate, isopropyl palmitate, propylene glycol, zinc soap and purified water.

Indications: Use as a topical aid in the treatment of acne.

Dosage and Administration: After cleansing the skin, smooth Sulfoxyl Lotion gently into the affected areas, once daily for three days. If no discomfort is felt, frequency of application can then be increased to twice daily. The amount of drying and desquamation can be modified by adjusting the dosage schedule.

Contraindications: Patients with a known sensitivity to benzoyl peroxide, sulfur or any of the other formulation ingredients should not use these medications.

Precautions: For external use only. Avoid contact with eyes, mucous membranes and sensitive areas of the neck. Notify physician if excessive dryness or irritation occurs or increases.
Keep from heat.

Caution: Patients should be warned that these formulations may bleach colored linens, towels and apparel.

How Supplied: 1.0 ounce plastic bottles.

Caution: Federal law prohibits dispensing without prescription.

Benoxyl® 5 and 10 Lotion: Benoxyl 5 contains 5% benzoyl peroxide and Benoxyl 10, 10% benzoyl peroxide in a grease-free washable lotion base.

How Supplied: 1 oz. and 2 oz. plastic bottles.

PanOxyl® 5, PanOxyl® 10 ℞

Composition: PanOxyl 5 contains 5% Benzoyl Peroxide. PanOxyl 10 contains 10% Benzoyl Peroxide. PanOxyl 5 and PanOxyl 10 also contain 6% polyoxyethylene lauryl ether and 40% ethyl alcohol in a gel base formulated with colloidal magnesium aluminum silicate, hydroxypropylmethylcellulose, citric acid and purified water.

Action and Uses: The topical use of PanOxyl 5 and PanOxyl 10 provides therapeutic control of acne through drying and desquamative action, as well as providing antiseptic activity.

Indications: Use as an aid in the treatment of acne.

Dosage and Administration: Apply 1 or more times daily to affected areas. Washing the face with soap and water prior to application greatly enhances the efficacy of the medication.

Contraindications: Patients with a known sensitivity to Benzoyl Peroxide should not employ these medicatons.

Precautions: For external use only. Avoid contact with the eyes or mucosal membranes. Very fair individuals should always be started on a single application at bedtime, allowing the medication to remain on the skin overnight. PanOxyl may bleach colored fabrics.

How Supplied: 2 oz. and 4 oz. plastic tubes.

Caution: Federal law prohibits dispensing without prescription.

Th. tt. Dimtn_iun. of Acne Care

The widest range of benzoyl peroxide formulations gives you maximum therapeutic flexibility

lew Sulfoxyl® Lotion

he drying and desqua-iating effects of sulfur dded to benzoyl per-xide can be particu-rly valuable in acne omplicated by exces-ve oiliness. "...Sulfur ith benzoyl peroxide .produces a greater eratolytic effect than ither substance lone."[1] The exfoliative roperties of sulfur can elp benzoyl peroxide penetrate deeper nto sebaceous folli-les.

wo Strengths:
ulfoxyl® Lotion Regu-r (5% benzoyl perox-le and 2% sulfur) and ulfoxyl® Lotion Strong 0% benzoyl peroxide nd 5% sulfur) in a rease-free washable ase.

Benoxyl® Lotion

A good way to start benzoyl peroxide therapy. Benzoyl peroxide alone has been described as "a triple action drug: (1) it suppresses *C. acnes* in vivo; (2) it is comedolytic and (3) it is a counter-irritant."[3]

Two Strengths
Benoxyl® 5 Lotion (5% benzoyl peroxide) and Benoxyl® 10 Lotion (10% benzoyl peroxide) in a grease-free washable base.

PanOxyl® Gel

"The most potent forms of benzoyl peroxide are the new alcohol gels such as PanOxyl. Once the gel is applied to the skin, the solvent evaporates and deposits a concentrated form of depot free-radical oxygen which...is capable of penetrating into the sebaceous follicles and suppressing the *C. acnes*. This topical agent is much more effective in suppressing the fatty acids and the bacterial counts than systemic tetracycline and also produces a more rapid clinical improvement... No new lesions usually appear after 3 weeks and after 2 months the patient is usually free of the acne problem."[2]

Two Strengths:
PanOxyl® 5 Gel (5% benzoyl peroxide) and PanOxyl® 10 Gel (10% benzoyl peroxide) in an alcohol gel base.

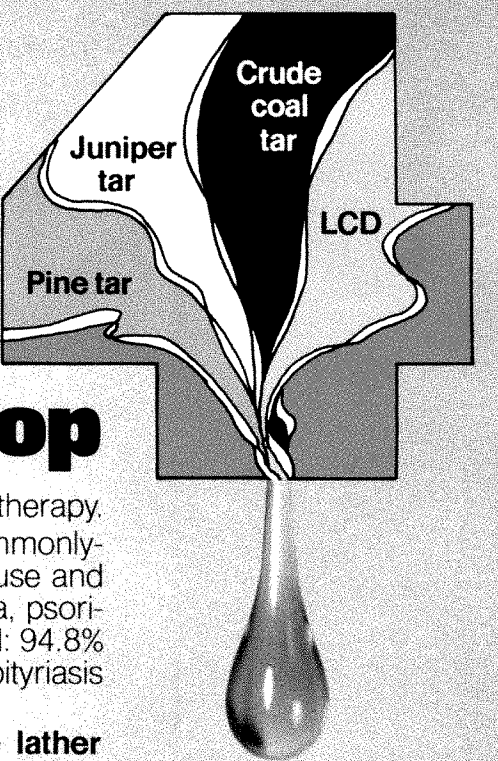
Tars have an important place in the management of seborrhea and psoriasis, but there is no clear cut agreement on when to use which.
A prudent approach:

Four tars in every golden drop



Now, a spectrum of tars maximizes the benefits of tar therapy. Polytar® Shampoo combines four of the most commonly-prescribed tars in one formula that is pleasant to use and therapeutically effective against dandruff, seborrhea, psoriasis and pityriasis capitis. Excellent results reported: 94.8% "very good" and 5.2% "good" in one study of both pityriasis capitis and psoriasis.*

And patients are pleased with the pure white lather that is as esthetically pleasing as a fine cosmetic and leaves hair lustrous and manageable.

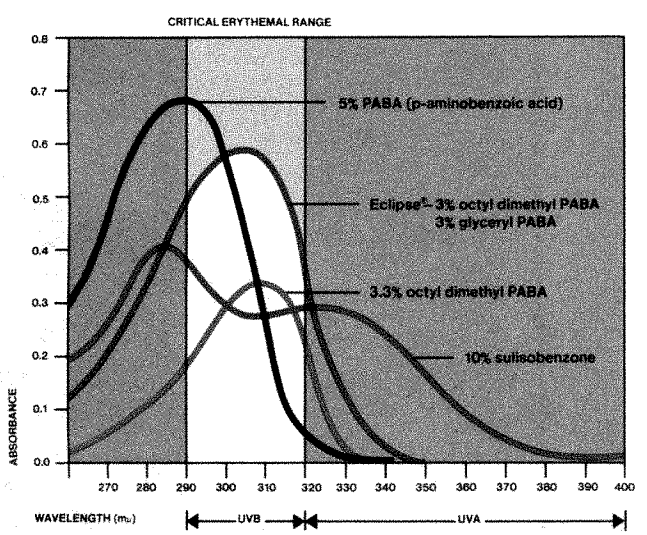
ECLIPSE®

(3% glyceryl PABA and 3% octyl dimethyl PABA)

For your patients

who can't-or won't-stay out of the sun.

For some, it's occupation. For others, the social desirability of a tan. Whatever the reason, many of your patients may be spending more time in the sun than you'd like.



Unique Eclipse formulation combines two PABA derivatives for maximum UVB absorption.

They need Eclipse—a highly effective sunscreen that works immediately upon application, resists wash-off, and contains our exclusive Aquacare® base to help relieve sun and wind-dried skin.

Can other sunscreens do all that? Take a minute to read the labels: we're confident you'll recommend Eclipse.

- Absorbs more than 99% of erythemogenic solar UVB.
- Spreads smoothly and predictably for even protection.
- Permits slow tanning.
- Resists wash-off; protects after swimming or sweating.
- Formulated in Aquacare® to relieve sun and wind-dried skin.

Aristocort®

Triamcinolone Acetonide Topicals

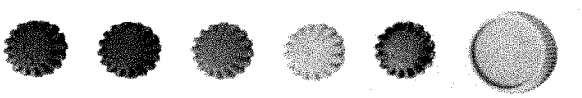
a form and strength for every patient....every type of steroid-responsive dermatosis

A standard for effectiveness in fluorinated topicals.

The first triamcinolone preparation to remove common sensitizers—contains no parabens, phenol preservatives, lanolin.

One of the most economical topical steroids available.

In cosmetically-pleasing forms that have become traditional patient favorites.



0.5% Cream	0.5% Ointment	0.1% Cream	0.1% Ointment	0.025% Cream	0.1% Gel

Indications: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.
Contraindications: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.
Warnings: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.
Precautions: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.
Adverse Reactions: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.
Supplied: *Cream 0.5%*—Per Gm.: triamcinolone acetonide 5 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.025%*—Per Gm.: triamcinolone acetonide 0.25 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; all potencies are in a water base of mono and diglycerides, squalane, polysorbate 80 USP, polysorbate 60, cetyl esters wax NF, stearyl alcohol USP, Tenox II, and sorbitol solution USP. *Ointment 0.5%*—Per Gm.: triamcinolone acetonide 5 mg.; inactive ingredient: white petrolatum; *Ointment 0.1%*—Per Gm.: triamcinolone acetonide 1 mg.; inactive ingredient: white petrolatum. *ARISTOGEL® Gel 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., 1.8% benzyl alcohol as preservative; inactive ingredients in a water base: polysorbate 80 USP, polyoxyethylene (20) cetyl ether, glycerin USP, and citric acid USP.

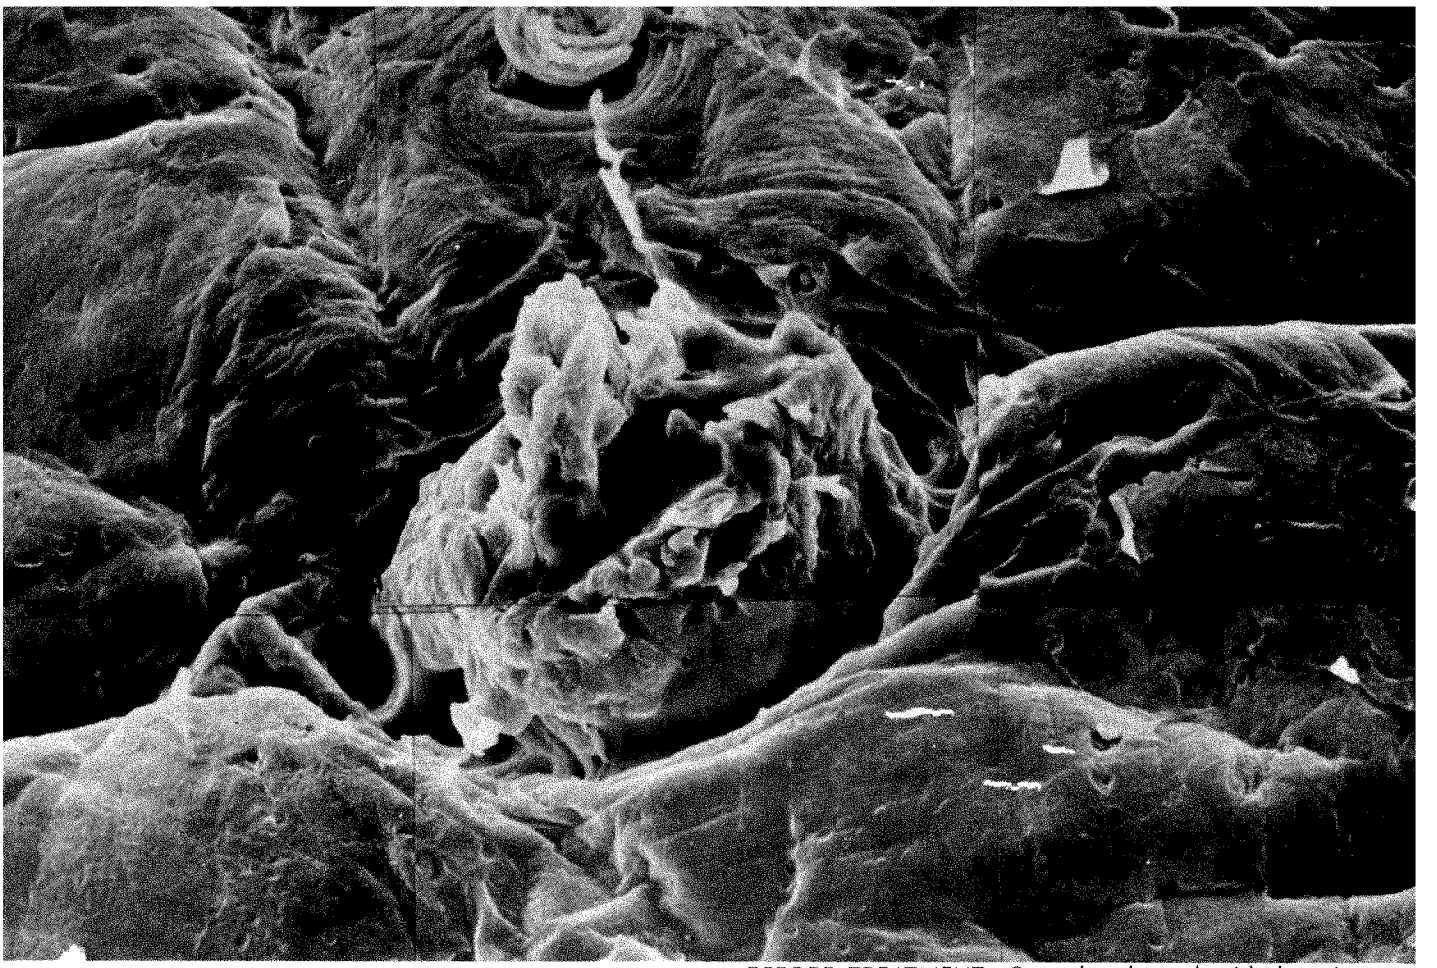
Pearl River, New York 10965



BEFORE TREATMENT: Comedo plugged with keratinous debris. Directly above is a smaller comedo, and in the lower left hand corner a vellus hair is apparent. Note absence of sharp lines of demarcation between layers of cells.*

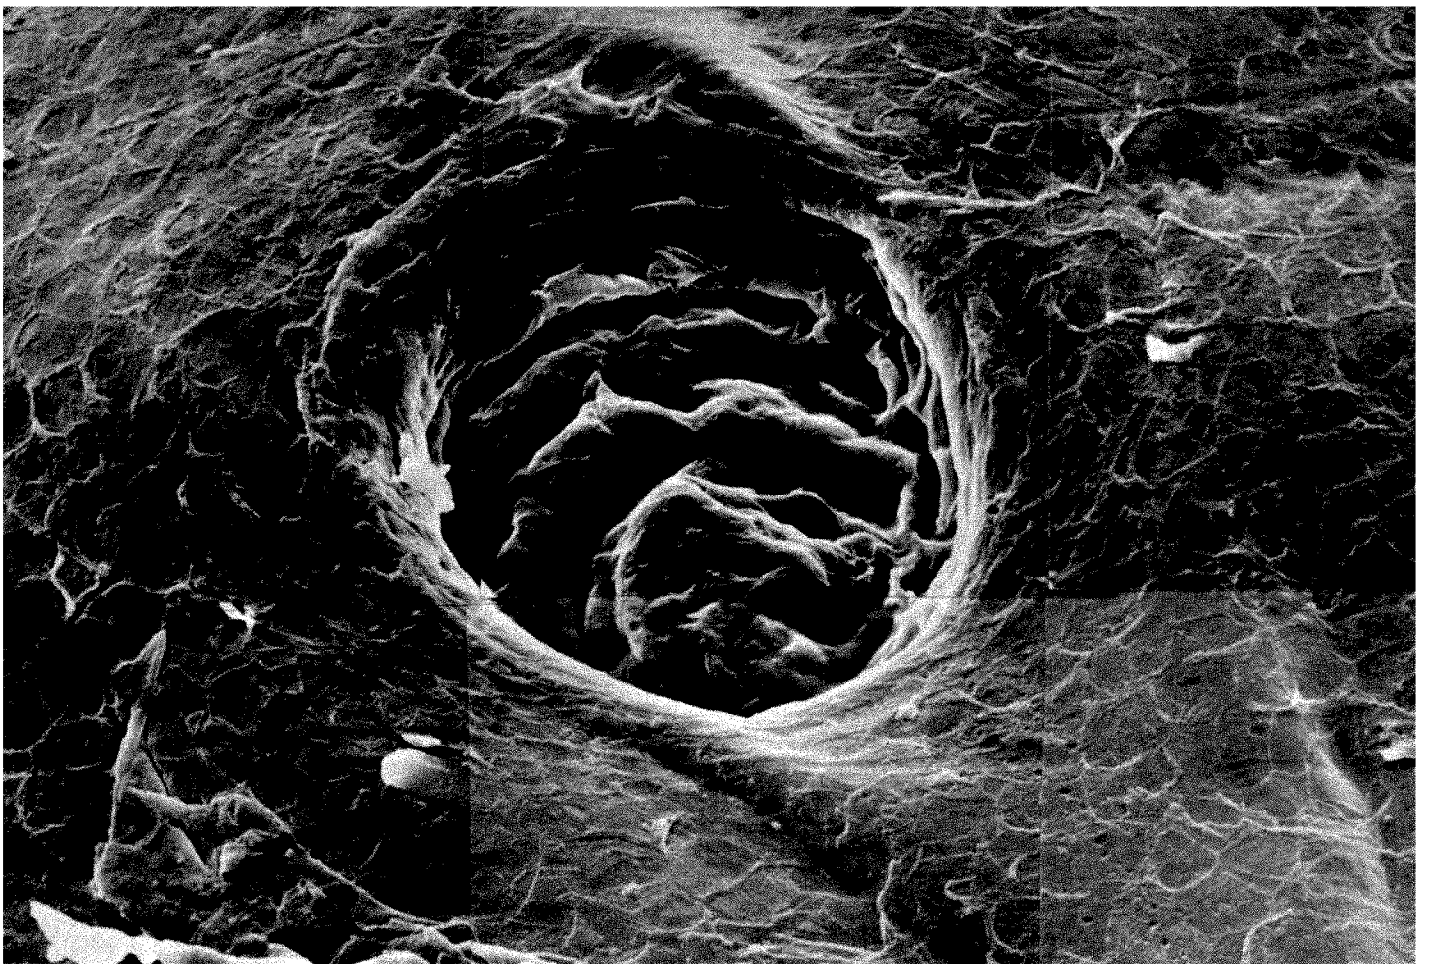
Pernox® Begins to Improve an Acne Lesion in 2 Days

Rapid resolution of an acne lesion is graphically demonstrated with Scanning Electron Microscopy.

We formulated Pernox® Abradant Scrub to make it effective yet gentle enough for acne skin.

Patients respond to Pernox rapidly, often noticing improvement after the first wash. Pernox Scrub/Lotion is a unique combination of therapeutic agents to emulsify oil and desquamate affected areas. Both forms of Pernox offer significant patient benefits.

Pernox® Lotion offers less desquamation and additional flexibility for your therapeutic acne regimen.



AFTER 2 DAYS: Depth of orifice indicates removal of plug in both large central and smaller top comedo. Surface desquamation and excellent hexagonal demarcations of individual epithelial cells are apparent.*

Pernox . . . an acne regimen formulated to give you an alternative to your present acne therapy or to be used adjunctively with other topical modalities for acne. Washing varies from patient to patient. You determine the regimen by frequency of washing and the amount of water used during the wash.

INDICATIONS: Acne vulgaris, oily skin, comedones.
CONTAINS: Gentle abradant microfine granules of polyethylene, 2% sulfur, 1.5% salicylic acid in SEBULYTIC® brand of unique penetrating surface-active combination of soapless cleansers and wetting agents.
CONTRAINDICATIONS: Not indicated when acute inflammation is present or in nodular or cystic acne.
ADMINISTRATION AND DOSAGE: After wetting the skin, PERNOX is applied with the fingertips and massaged into the skin for about one-half to one minute. The skin is then thoroughly rinsed. Used one to two times daily, or as directed.
CAUTION: If undue skin irritation develops or increases, adjust usage schedule or discontinue use. If necessary, anti-inflammatory measures may be used after discontinuance. For external use only. Contact with eyes should be avoided. In case of contact, flush eyes thoroughly with water.

S/J

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

Cutaneous Manifestations of Patients With Epidermal Nuclear Staining and High Titer Serum Antibody to Ribonuclease-Sensitive Extractable Nuclear Antigen

James N. Gilliam, MD, Stephen D. Prystowsky, MD

• Fifteen patients with epidermal nuclear staining on direct immunofluorescence of normal skin and high titer serum antibody to ribonuclease-sensitive extractable nuclear antigen (ENA) had diffuse nonscarring and focal alopecia, abnormal pigmentation, swollen hands with sclerodactyly, and chronic cutaneous lupus erythematosus (LE) as the most common dermatologic features. Direct immunofluorescence of normal, unexposed skin revealed a particulate ("speckled") epidermal nuclear staining pattern in all 15 patients and subepidermal immunoglobulin deposits in 5. Ribonucleoprotein antibodies in high titer are associated with this characteristic type of epidermal nuclear staining. These findings provide easily detectable markers for a less aggressive subset of LE characterized by distinctive clinical and laboratory features consistent with mixed connective tissue disease.

(*Arch Dermatol* 113:583-587, 1977)

Sharp and co-workers[1] have recently described a group of patients designated as having mixed connective tissue disease (MCTD) with benign features often compatible with systemic lupus erythematosus (SLE) but suggestive of scleroderma or polymyositis or both. Most of these patients had considerable hypergammaglobulinemia and they all had high titer antibody to a saline-soluble (extractable) nuclear antigen, referred to as ENA.

Since many patients with typical features of SLE have similar ENA antibody titers, attempts were made to differentiate the antibody of MCTD from SLE by enzymatic treatment of the ENA with ribonuclease (RNase).[2] In SLE, the ENA antibody reaction was unaffected by RNase treatment of the antigen. However, such treatment greatly reduced or abolished the reaction in MCTD. This finding suggested that patients with MCTD had antibody to an RNase-sensitive antigenic component of the ENA whereas in patients with typical SLE the antibody was to an RNase-resistant ENA. These and other studies[3-5] have shown that at least two distinct antigens are present in the ENA. One is a ribonucleoprotein (RNP) that is sensitive to RNase and trypsin; the other is resistant to RNase and appears to be identical to the previously described glycoprotein Sm antigen.[3] In patients with MCTD, the antibody is directed to the RNase-sensitive RNP antigen. The clinical course of patients with this syndrome is usually benign and many of the clinical manifestations disappear with steroid therapy.

In direct immunofluorescence studies of apparently normal skin from patients with rheumatic diseases, particulate ("speckled") epidermal nuclear staining has been reported.[6-8] This epidermal nuclear staining was found to correlate with high titer antibodies to both the RNase-sensitive (RNP) and RNase-resistant (Sm) ENA.[9-11] This finding brought to our attention a group of patients with anti-RNP antibodies. The purpose of this article is to describe the cutaneous manifestations in these patients with epidermal nuclear staining and high titer antibody to RNP.

uninvolved, nonexposed skin were studied. Fifteen of the 20 patients had high titer antibody to an RNase-sensitive ENA (RNP); data are reported only for these 15 patients. This group consisted of 14 women and 1 man; their ages ranged from 14 to 61 years, with a mean age of 36 years. Thirteen were black and 2 were white. All of the patients were personally examined by one of us (JNG) on one or more occasions.

Immunologic Studies

Antinuclear antibodies were determined by the method of Holborow et al[12] using fresh rat kidney sections and human squamous carcinoma cells (BK) as the substrate. Total hemolytic complement (CH50) was measured by the microtitration technique of Nelson et al,[13] and antibodies to double-stranded DNA (anti-nDNA) were measured by the method of Ginsberg and Keiser.[14]

The extractable nuclear antigen was determined by the hemagglutination method of Sharp et al.[2] This test was performed with ENA-coated sheep erythrocytes before and after RNase treatment. A fall in titer of more than two dilutions after treatment was interpreted as RNase sensitivity and was an indication of antibody to RNP. Immunoglobulin deposits at the dermal-epidermal junction were detected by direct immunofluorescence on biopsy specimens of normal, unexposed skin as previously described.[15]

RESULTS

Table 1 gives the cutaneous manifestations in the 15 patients with the MCTD syndrome. Alopecia was observed in 10 (67%) patients and was usually nonscarring and diffuse (Fig 1). Focal hair loss and alopecia areata were also observed. The alopecia was unusually persistent and failed to correlate closely with disease activity in contrast to the diffuse alopecia of acute SLE. Pigmentary disturbances were found in 10 (67%) patients. Three had hypopigmentation with follicular retention of pigment as in scleroderma or repigmenting vitiligo (Fig 2 and 3). Areas of hyperpigmentation (both diffuse and focal) were observed in seven additional patients. Sclerodactyly with swelling of the fingers that results in a tapered or sausage appearance was present in seven (49%) patients (Fig 4 and 5). Eight patients (53%) had cutaneous forms of

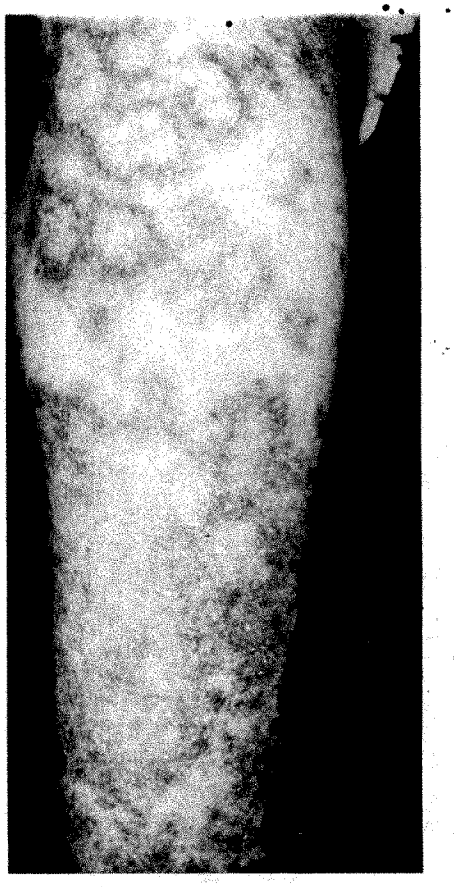

Fig 6.—Diffuse erythematous, nonscarring subacute cutaneous lupus erythematosus.

Table 2.—Clinical Features of Patients With Serum Antibody to RNase-Sensitive ENA* (RNP)†

Clinical Feature	No. of Patients	No. Positive	% Positive
Arthritis/arthralgia	15	14	93
Raynaud phenomenon	15	13	87
Lymphadenopathy	15	6	40
Serositis	15	6	40
Myositis	15	3	20
Pulmonary fibrosis	15	1	7
CNS disease	15	1	7
Renal insufficiency	15	0	0

*ENA indicates extractable nuclear antigen.
†RNP indicates ribonucleoprotein.

LE. Five (33%) had persistent, chronic scarring discoid-type lesions. Two patients had the diffuse, nonscarring, erythematous, papulosquamous variety of subacute cutaneous LE (Fig 6). One patient had an acute malar (butterfly) eruption. One patient had cutaneous sclerosis that almost completely resolved with prednisone therapy.

Table 2 gives the clinical features of the 15 patients with high titer antibody to RNP. Arthritis or arthralgia (93%) and the Raynaud phenomenon (87%) were present in most patients. Lymphadenopathy (40%) and serositis (40%) were also common features. Myositis with increased muscle enzyme values was noted in only three (20%) patients. Clinically notable interstitial lung disease with reduced diffusion capacity was observed in one case (7%). Pulmonary function studies were not done on the other 14 patients. One patient had episodes of psychosis and seizures. Renal insufficiency, defined as azotemia or a creatinine clearance below 85 ml/min, was not observed.

Table 3 and Figure 7 show the laboratory findings for these patients. All had high titer antinuclear antibodies with a particulate (speckled) staining pattern. Extractable nuclear antigen antibody titers ranged from 1:32,000 to > 1:500,000 in serums from all 20 patients with epidermal nuclear staining (Fig 7). In 32 patients with SLE with positive antinuclear antibody test results and negative ENA antibody or titers below 1:16,000, skin biopsy specimens failed to show epidermal nuclear staining (Fig 8). Hypergammaglobulinemia was present in 12 (80%) patients. Subepidermal immunoglobulin in normal, nonexposed skin was observed in five (33%) patients. Depressed CH50 occurred in three (20%) patients. Lupus erythematosus cells were seen in only two of the ten patients tested. Rheumatoid factor was present in two (13%) patients. None of these patients had sub-

stantially elevated levels of antibody to native DNA.

COMMENT

Ribonucleoprotein antibodies in high titer and epidermal nuclear staining seem to provide readily detectable indicators for a less aggressive connective tissue disease.[5] These patients often have the clinical features of MCTD as described by Sharp and co-workers.[1,2] Such "overlap" syndromes have been described previously,[16,17] but Sharp et al[2] were the first to associate the RNP antibody with certain distinctive clinical and laboratory features. The most striking clinical manifestation associated with high titer RNP antibody seems to be the Raynaud phenomenon. Our data confirm the apparent low incidence of renal involvement associated with RNP antibodies.[2,18-20]

In addition to epidermal nuclear staining, RNP antibody is associated with a mixture of cutaneous features. A diffuse, nonscarring alopecia was observed in 67%. In contrast, Tuffanelli and Dubois[21] found a similar type of hair loss in only 21% of 520 unselected patients with classic SLE. Hyperpigmentation or hypopigmentation or both was present in 67% of our patients with RNP antibody. In comparison, Tuffanelli and Dubois[21] observed hyperpigmentation in only 8% of their patients with SLE. However, Tuffanelli and Winkelmann[22] noted pigmentary abnormalities in 32% of 727 cases with systemic scleroderma. Sclerodactyly with swelling of the hands and a tapered or sausage appearance of the fingers was present in 47% of the patients in

this study, a finding well described in MCTD by Sharp and co-workers.[2] An unexpected and previously unrecognized finding was that one third of these patients had chronic destructive or discoid-type skin involvement. Discoid-type lesions are present in only 10% to 15% of unselected patients with SLE.[23,24] We have recently shown that these patients with SLE with discoid-type LE skin lesions also have a low incidence of DNA antibodies and insignificant renal disease.[25] It is of interest that Dubois et al[17] noted that 43% of the patients with a scleroderma-SLE overlap syndrome had discoid skin lesions.

Antibody to RNP seems to be another in a growing list of immunologic markers associated with certain distinct clinical manifestations. Antibodies to native DNA are associated with lupus nephritis[26]; antibodies to the Sm antigen are found almost exclusively in SLE.[27] Marker antibodies may be associated with certain forms of scleroderma[28,29]; some of these are directed to uracil and are thus specific for single-stranded RNA.[28] Specific immunofluorescence staining patterns may correlate with many of these autoantibodies and thus aid in diagnosis and management.[30]

It seems likely that future investigation may reveal antigen-antibody systems that are related to other distinct connective tissue disease syndromes. Since the MCTD syndrome has many features of typical SLE, the early differentiation of this group with a less aggressive clinical course, absence of renal disease, and good response to steroids is important for prognostic purposes. Epidermal nuclear staining and RNP antibodies seem to provide easily detectable immunologic markers for such cases.

Effect of Sodium Salicylate and Indomethacin on Methotrexate-Serum Albumin Binding

J. Richard Taylor, MD, Kenneth M. Halprin, MD

• **Approximately 60% of methotrexate in serum is protein bound and this binding occurs primarily to serum albumin. The fraction of methotrexate bound remains relatively constant despite changes in free methotrexate concentrations over the range observed clinically.**

Indomethacin did not influence methotrexate-albumin binding, but salicylate in therapeutic concentrations produced a 20% to 60% decrease in binding. The clinical significance of these findings for patients requiring concomitant methotrexate and salicylate is discussed.

(*Arch Dermatol* 113:588-591, 1977)

The affinity of a drug for plasma proteins and the extent to which it is bound at therapeutic concentrations can greatly influence its distribution, excretion, and interaction with other drugs. Methotrexate is frequently used in the treatment of severe psoriasis. Studies of methotrexate absorption and excretion exist,[1,2] but little is known about methotrexate binding to plasma proteins and how this binding is influenced by concomitant ingestion of other medications. Psoriatic arthritis is frequently associated with severe psoriasis and may require the use of salicylates or indomethacin in addition to methotrexate. The purpose of this study was to investigate the influence of these drugs on methotrexate binding.

This was done in the following manner. We first determined that methotrexate is bound predominantly to the albumin fraction of serum protein. This was done by separating serum electrophoretically and determining the methotrexate concentration in the various fractions. We next studied the influence of albumin concentration and methotrexate concentration on binding. Binding was determined by ultrafiltration with the use of a membrane that allowed unbound methotrexate to pass but that retained albumin and any methotrexate bound to it. After these variables of methotrexate-albumin binding in this system had been determined, we studied the effects of adding sodium salicylate or indomethacin on binding.

MATERIALS AND METHODS

Drugs

Tritium-labeled methotrexate (methotrexate $-3',5'-H3(n)$ sodium salt; specific activity, 13 Ci/mmole) was obtained and after thin-layer chromatographic purification was determined to be greater than 98% radiochemically pure. Nonradioactive methotrexate, sodium salicylate, and indomethacin were obtained in crystalline form. All drugs were buffered with phosphate buffer with a pH of 7.4 and prepared so that the final solution had an ionic strength of 0.16 M.

Proteins

Normal human serum control was obtained lyophilized and was reconstituted just before use by the addition of distilled water. Crystalline human serum albumin was obtained and was found to be electrophoretically pure and to contain 0.05 mM of fatty acid per millimolar of albumin. Various albumin concentrations were prepared by dissolving an appropriate amount

Accepted for publication Oct 13, 1976.

of crystalline albumin in 0.16 M phosphate buffer (pH of 7.4).

Which Serum Protein Binds Methotrexate?

To determine which serum protein binds methotrexate, the following was done. Sufficient tritium-labeled methotrexate (specific activity, 13 Ci/mmole; 0.5 mCi/ml) was added to 5 ml each of normal human serum, 5% normal human albumin, and phosphate buffer to produce a final concentration of 5 μCi/ml. The three solutions were incubated at 25 C with occasional gentle mixing for two hours to assure equilibration. Two 1 × 3-inch cellulose acetate-coated mylar strips were prepared from each solution by placing 2 μl one half inch from the end (Fig 1). The strips were subjected to electrophoresis in 0.075 M barbital buffer with a pH of 8.6 for 45 minutes with 100 volts dc. After migration, one set of strips was fixed in 5% acetic acid for ten minutes, dried, and set aside for scintillation counting. The duplicate set of strips was stained for protein with ponceau S dye (0.09% ponceau S, 1.34% trichloroacetic acid, 1.34% sulfosalicylic acid), destained in 5% acetic acid, and cleared in glacial acetic acid-ethyl acetate (7:3 v/v).

The location of the stained protein in the stained set of slides was used to divide the unstained set into appropriate sections for counting. Each resulting section was dissolved in a scintillation vial containing 15 ml of modified Bray solution, and the radioactivity present was determined in a liquid scintillation spectrometer. Quench variations among samples were corrected using an automatic external standard.

Methotrexate-Albumin Binding

Methotrexate binding to serum albumin was determined by ultrafiltration using a model 8-MC ultrafiltration cell equipped with a PM-10 membrane and 2 kg/sq cm pressure was maintained with nitrogen gas. (PM-10 membrane retains all molecules greater than a molecular weight of 10,000. Membranes were presoaked in distilled water for 24 hours and transferred to buffer one to two hours before use.) This method for determining ligand-protein binding has been described by several investigators,[3-5] and is an accepted method for such studies.[6] The model 8-MC ultrafiltration cell has a 5-ml sample chamber to which the membrane is attached and is provided with a magnetic stirring bar to prevent concentration polarization of the protein retent over the membrane. The cell is also equipped with a 100-ml reservoir as part of the closed pressurized system. As the stirred sample is filtered through the membrane, reservoir solution enters the sample chamber at the same rate that ultrafiltrate is formed and, therefore, the retent is maintained at a constant volume and is continually exposed to fresh reservoir solution.

Ultrafiltrate was collected in separate preweighed tubes by a fraction collector. When the ligand concentration in the ultrafiltrate equals its concentration in the reservoir solution, binding equilibrium has occurred. At equilibrium, aliquots of reservoir solution, retent, and ultrafiltrate were collected, their volumes determined, and the amount of drug and protein present measured. Albumin concentrations were determined fluorometrically with 1-anilinonaphthalene-8-sulfonic acid using the method described by Elevitch.[7] Methotrexate was determined by placing 100 μl of each sample in vials containing 15 ml of modified Bray solution and comparing the activity present with known dilutions of tritium-labeled methotrexate in a liquid scintillation spectrometer. Variations in quench among samples were corrected by use of an automatic external standard.

Effect of Salicylate and Indomethacin on Methotrexate-Albumin Binding

In these experiments, 5% serum albumin was allowed to reach equilibrium binding with a reservoir solution that contained 10^{-6}M methotrexate (0.1 μCi/ml). After removal of 100 μl of retent for determination of binding without drug, the reservoir solution was replaced with phosphate buffer containing the same concentration of methotrexate as before but to which appropriate amounts of salicylate or indomethacin had also been added. Ultrafiltration was continued until equilibrium was again obtained and binding of methotrexate to albumin again determined.

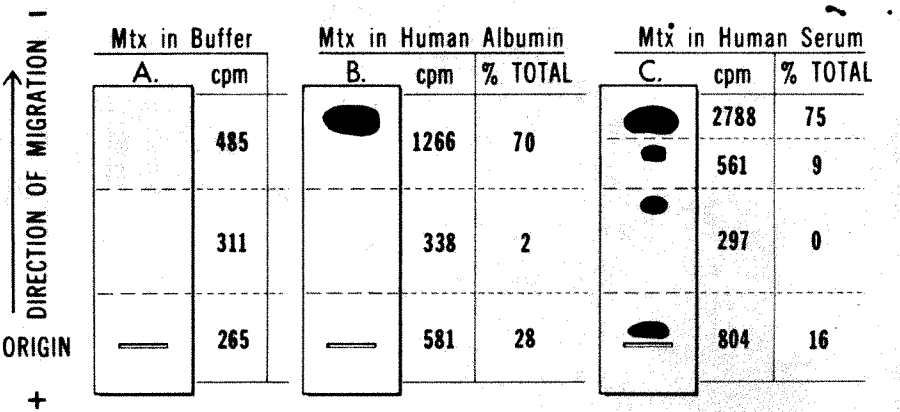

Fig 1.—Diagram of distribution of methotrexate after electrophoresis on cellulose acetate strips. For procedure and calculations see text. Dark areas indicate stainable proteins and dashed lines indicate strip separation for determination of radioactivity.

RESULTS

Serum Protein Fraction Binding Methotrexate

Figure 1 shows the protein separation and corresponding counts per minute of tritium-labeled methotrexate present in the different sections of the cellulose acetate strips. Nonspecific binding of tritium-labeled methotrexate to the strips occurred as indicated by the counts per minute present in the three sections of strip A. These background values were subtracted from the counts per minute present in corresponding sections of strips B and C before determining the percent of total counts per minute present in each.

Methotrexate is bound predominantly by albumin. The small amount of binding to other serum proteins is insignificant compared with albumin. Normal human serum albumin was therefore used for the equilibrium studies.

Methotrexate-Albumin Binding

To determine the effect of albumin concentration on methotrexate binding, 10^{-6}M methotrexate (0.1 μCi/ml, tritium-labeled methotrexate) was equilibrated with albumin in concentrations of 2 to 7 gm/100 ml and the fraction bound was determined. The results are illustrated in Figure 2. The fraction of methotrexate bound is proportional to the albumin concentration ranging from 30% with an albumin concentration of 2 gm/100 ml to more than 70% with an albumin concentration of 7 gm/100 ml. Ap-

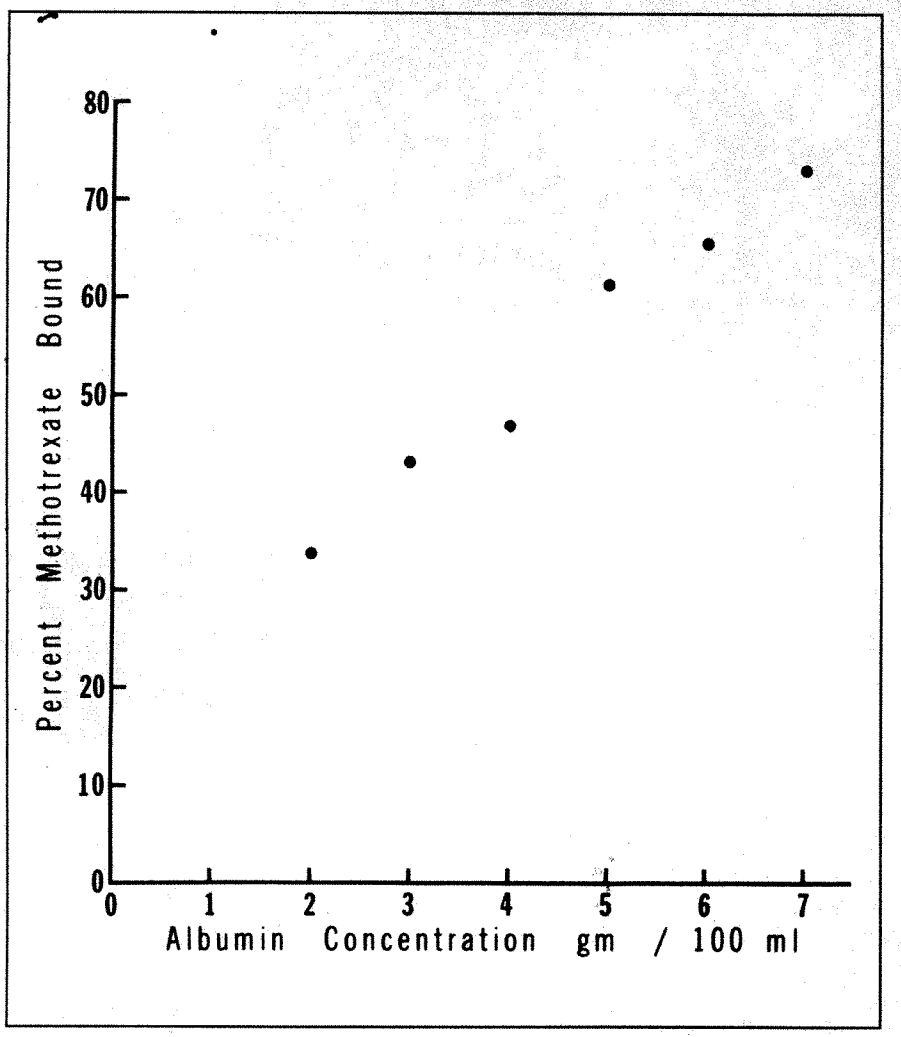

Fig 2.—Percent of methotrexate bound at albumin concentrations from 2 to 7 gm/100 ml. Free methotrexate concentration, 10^{-6}M.

Table 1.—Influence of Methotrexate Concentration on Binding to 5% Albumin

*The methotrexate concentrations for these experiments were observed clinically.

proximately 50% to 60% of the methotrexate is bound at normal albumin concentrations of 4.5 to 5.5 gm/100 ml.

Table 1 gives the percent of methotrexate bound at free methotrexate concentrations from 1×10^{-8} to 5×10^{-3}M. The albumin concentration was 5 gm/100 ml for all determinations. When more than one determination was done at the same methotrexate concentration, the results were averaged. The number of determinations performed at a given free methotrexate concentration and when possible the standard deviation are also included in Table 1. The percent of methotrexate bound is remarkably constant and does not begin to decrease until very high free methotrexate concentrations are used. This decrease is of only theoretical interest since binding remains constant at methotrexate concentrations seen clinically (2×10^{-7} to 5×10^{-6}M).

Effect of Salicylate and Indomethacin on Methotrexate-Albumin Binding

The percent of methotrexate bound to human serum albumin is decreased in the presence of salicylate. The binding of 1×10^{-6}M methotrexate to 5 gm/100 ml of albumin with four concentrations of salicylates is given in Table 2. These concentrations of salicylate are all comparable to serum levels of salicylate that might be observed clinically. As the salicylate concentration increases, a greater amount of bound methotrexate is displaced from albumin as indicated by the decrease in the percent of methotrexate bound.

The influence of a therapeutic concentration of indomethacin on the same concentrations of methotrexate and albumin used as just described was also studied and the results are included in Table 2. There was no significant change in binding in the presence of 0.014 M of indomethacin.

COMMENT

A considerable amount of literature exists in the field of drug-protein binding.[4-6,8,9] Most of these studies describe systems that react in a

Table 2.—Change in Methotrexate-Albumin Binding With Various Concentrations of Salicylate and Indomethacin

Salicylate Concentration		% Methotrexate Bound		Indomethacin Concentration		% Methotrexate Bound

33	2.06×10^{-3}	23	68	...	...	...	...

predictable manner to a given change in drug or protein concentration. Newer analytical methods for measuring small concentrations of commonly used drugs have demonstrated several systems where binding to serum appears to be independent of the free drug concentrations,[10-12] which is analogous to methotrexate-albumin binding found in this study. Approximately 60% of methotrexate in serum is bound and this binding occurs primarily to serum albumin. Others have reported 70%[13] and 50%[14] bound and substantiate our finding that percent binding varies little with changes in free methotrexate concentration over the range observed clinically.

Indomethacin did not influence methotrexate binding, but salicylate in concentrations seen under clinical conditions displaced bound methotrexate. Methotrexate binding was decreased 20% to 60% by the salicylate concentrations tested. The clinical implications of these findings are not known and it is not possible to predict changes that might occur in vivo from these limited in vitro studies. In vivo, displaced methotrexate is rapidly redistributed into the total body water and is available for interaction with other tissues and for more rapid excretion. It is probable that even total displacement of bound methotrexate by salicylate would result in only a slight and transient increase in free methotrexate concentrations in serum because of these factors. Dettli[15] has studied the pharmacokinetics of drug interaction in some detail and concludes that for displacement from binding sites to be of practical significance, the displaced drug must originally be 90% bound and once displaced its distribution volume should not exceed the volume of the extracellular water. From these criteria, displacement of bound methotrexate would not be of practical significance.

Numerous articles are available that deal specifically with drug interaction[8] or with this as one of the many types of adverse drug reactions.[16] Many contain extensive tabulations of potential drug interactions. Unfortunately, few contain sufficient information to allow critical appraisal of the likelihood or clinical significance of a given interaction. When the original data from which these lists were developed is examined, one finds animal studies not directly applicable to man, clinically unimportant interactions, isolated case reports of questionable significance, and some instances of frank speculation.[17,18] Methotrexate-salicylate interaction invariably appears in these lists, and it, too, is based on a limited number of uncritical case reports.[19]

Although salicylate can displace methotrexate bound to serum albumin, the small transient increase in free methotrexate concentration produced would be of doubtful clinical significance. This is particularly true in the treatment of psoriasis where methotrexate is given once weekly and the dosage is determined by the patient's clinical response. Because of these factors, this potential drug interaction should not preclude the judicious use of these drugs concomitantly in patients requiring the effects of both substances.

Clinical and Histological Study of Coal Tar Phototoxicity in Humans

Kays H. Kaidbey, MD, Albert M. Kligman, MD, PhD

• **Coal tars of different origin were compared with regard to their capacity to cause a phototoxic reaction in human skin. The photosensitizing potencies were found to differ. Tars that were partially refined had less activity than crude coal tar. An extract of tar, liquor carbonis detergens, was the least photosensitizing.**

The phototoxic reaction to coal tar was found to be a two-stage process, an immediate wheal associated with sharp burning, followed by a raised, red, infiltrated lesion peaking at 24 to 48 hours. The phototoxic reaction was completely prevented when arterial blood flow was cut off.

The histological findings were prominently epidermal, with strong intracellular edema sometimes leading to microvesicles.

It seems a possibility that assaying phototoxic potentiality may provide a convenient measure of therapeutic efficacy of materials derived from coal tar.

(*Arch Dermatol* 113:592-595, 1977)

Physicians usually view phototoxic reactions as undesirable side effects of commonly administered drugs. The benefits of certain of these drugs, such as phenothiazines and tetracyclines, far outweigh the mischief they do and physicians continue to use them despite their phototoxic potentialities. Dermatologists, however, have adapted some photosensitizers to therapeutic advantage. The photosensitizing action of coal tar may be a factor in the Goeckerman[1] method of phototherapy for psoriasis.[2] Plant extracts containing phototoxic psoralens have been used for centuries in conjunction with sunlight to treat vitiligo. Recently, 8-methoxypsoralen has been shown to be effective in treating psoriasis both locally and orally in conjunction with long ultraviolet light.[3-5]

Curiously, long-standing familiarity with the photosensitizing properties of coal tar, whether in outdoor workers exposed to tars or in psoriatics undergoing the Goeckerman regimen, have seemed to stifle curiosity regarding the nature of the reaction. Pitch workers have long experienced an immediate stinging response (the smarts) after exposure to sunlight.[6] Clinicians, however, do not seem to be aware that immediate wheal reactions are characteristic of coal tar phototoxicity. Aside from realizing that photosensitization requires long ultraviolet rays (> 320 nm), little is known about the histopathology and pathophysiology of the reaction.

Because of its unwelcome appearance and odor, many efforts have been made to develop more agreeable tar products. The extent to which pharmacologic activity is sacrificed for cosmetic improvement is generally hard to estimate. That is unfortunate when one considers that tars are perhaps second only to corticosteroids in being the most widely prescribed topicals for diverse chronic dermatoses. Clinical assessments of efficacy are difficult and notoriously unreliable. No standards are available for determining the therapeutic potency of various tars except by clinical trial. We propose to show that phototoxic capacity can be readily measured in human skin and may provide a means for estimating the clinical efficacy of tars in chronic dermatoses.

MATERIALS AND METHODS

Subjects

The participants were adult, student volunteers between 20 and 30 years of age.

Light Source

Long ultraviolet light rays (UVA) were obtained from five 20-W blacklight fluorescent tubes housed in a reflecting bank. These emit a continuous spectrum beyond the sunburn range, with a peak output at about 360 nm. The source-to-skin distance was 2 inches and the intensity was 3.46 mW/59 cm as measured by a calibrated thermopile.

Coal Tar Phototoxicity

The phototoxic response was studied in 26 subjects each of whom received 50 mg of 5% crude coal tar in hydrophilic ointment to a 1-square inch site over the volar aspect of the forearm. The sites were occluded for two hours, cleansed with acetone-soaked gauze, and immediately exposed to UVA for ten minutes.

Phototoxic Assay

Details of the procedure have been given previously.[7] Briefly, 50 mg of the test material is applied uniformly with a glass rod to 1-inch squares of skin outlined with

adhesive tape on the volar aspect of the forearm. The site is then covered with a 1-sq inch patch of nonwoven cotton cloth. The forearm is then encircled with plastic film held securely in place by adhesive tape. Two hours later, the site is wiped with acetone-soaked gauze. Exposure to UVA for four minutes follows immediately (0.83 J/sq cm). Reactions were graded by one of us (K. K.) as follows: 0 indicated normal skin; 1, minimal erythema; 2, more intense erythema; and 3, intense erythema and edema. Each test site was graded at 24 and again at 48 hours and both readings were averaged. Student t test was used to test significance.

Comparison of Coal Tars

Five percent concentrations of seven different tars in hydrophilic ointment were assayed in each of eight subjects. The tars were applied randomly to the volar aspects of both forearms (seven sites per subject). We have shown previously that hydrophilic ointment is a particularly good vehicle for coal tar.[7] Samples of crude coal tar were obtained from four different manufacturers. These are putatively USP crude coal tars. In addition, two partially refined tars from two different manufacturers were evaluated. Liquor carbonis detergens was also secured.

Histopathology

A total of three biopsy specimens were obtained from each of four subjects. Three sites in each individual were sensitized with 5% crude coal tar in hydrophilic ointment and exposed to UVA for ten minutes. Biopsy specimens were obtained immediately after irradiation and after 24 and 48 hours. The specimens were fixed in a 10% formaldehyde solution and stained with hematoxylin-eosin and PAS.

Studies of Wheal Reaction

The possibility that histamine mediated the immediate wheal reaction was studied in the following ways. The tests were conducted on the volar aspect of the forearms, using 5% crude coal tar in hydrophilic ointment. The irradiation was extended to ten minutes to ensure the development of wheals.

Depletion of Skin Histamine.—Two and three tenth-centimeter squares of filter paper were saturated with an aqueous solution of compound 48-80 (0.07 mg/ml) and placed on the forearm of seven subjects. An iontophoretic current was applied at a current density of 0.19 ma/sq cm for three minutes. A similar application 15 minutes after the wheal subsided did not provoke a new wheal, indicating depletion of histamine stores in mast cells. Two hours after flattening of the wheal, 25 mg of the tar ointment was applied to one half-square inch areas for two hours and then irradiated in the usual way.

Phototoxicity of Coal Tars (5% Concentration in Hydrophilic Ointment)*

B	0.71 ± 0.15
Wright LCD	0.58 ± 0.15

*Phototoxicity measured by intensity of erythema and edema on a four-point scale: 0, normal skin; 3, intense erythema and edema.

†Each sample was obtained from a different manufacturer. LCD indicates liquor carbonis detergens.

‡Mean values represent averages of eight readings for each tar obtained at 24 and 48 hours after irradiation.

Antihistamine.—Five percent crude coal tar was applied to two sites for two hours in each of ten subjects. Thirty-five minutes before irradiation, one site was injected intradermally with 0.2 ml of chlorpheniramine maleate (1:1,000) in physiologic saline; the other received 0.2 ml of saline.

Influence of Corticosteroids

A 0.05% fluocinonide ointment (Lidex, Syntex) was applied to five subjects under an occlusive dressing for 24 hours before inducing a phototoxic response. A control site received white petrolatum. In another four subjects, the phototoxic reaction was evaluated five hours after a single orally administered dose of 12 mg of triamcinolone acetonide.

Influence of Arterial Occlusion

A sphygmomanometer cuff was placed on the upper arm of six subjects and inflated to greater than arterial pressure five minutes before irradiation of a tar-treated site. The blood supply was curtailed during the entire ten-minute irradiation period. A similar tar site over the opposite arm served as the control.

RESULTS

Evolution of the Phototoxic Response

The gross events were similar in all subjects and developed in the following pattern. Within one to two minutes of exposure, the subject experiences a sharp burning sensation in the absence of any visible sign. The burning is similar to a hot object placed close to the skin. It increases in intensity and becomes very pronounced after four to six minutes, at about which time erythema becomes apparent with a surrounding flare. By the end of the exposure time (ten minutes) a solid erythematous wheal develops, localized to the irradiated site and surrounded by an erythematous flare. The burning gradually dissipates after irradiation stops and is replaced by a slight dull pain. The wheal resolves in 30 to 60 minutes. During the next two to four hours, the flare regresses, becoming exactly localized to the site of irradiation. After about 12 hours, the erythema deepens and the site becomes palpably raised. These changes peak in 24 to 48 hours. Thus, the phototoxic reaction is a two-stage process: an immediate wheal followed by a late infiltrated reaction. In 5 of the 26 subjects who had a darker complexion an immediate response developed, namely, erythema, flare, and pain without whealing. They also had a mild delayed response. Intense reactions healed slowly over a period of 10 to 14 days, after becoming crusted. Pigmentation became evident seven to ten days after exposure and was more intense in the dark-complexioned individuals. In three of these subjects, pigmentation was still present three months after exposure.

Comparison of Tars

The tars differed appreciably in regard to the intensity of the late reaction (Table). Two partially refined tars were equivalent but significantly less phototoxic than the crude tars ($P < .05$). Liquor carbonis detergens was less active than the refined products.

Histopathology

Biopsy specimens obtained from wheals immediately after irradiation showed only dilated vessels and perivascular edema in the upper dermis. By 24 hours, epidermal changes became evident. These ranged from moderate spongiosis with intracellular

Fig 1.—Twenty-four-hour reaction. Spongiosis and intracellular edema are notable in basal portion of epidermis whereas necrobiotic changes are underway at top. Dermal vessels are dilated but inflammatory cells are meager (hematoxylin-eosin, original magnification ×210).

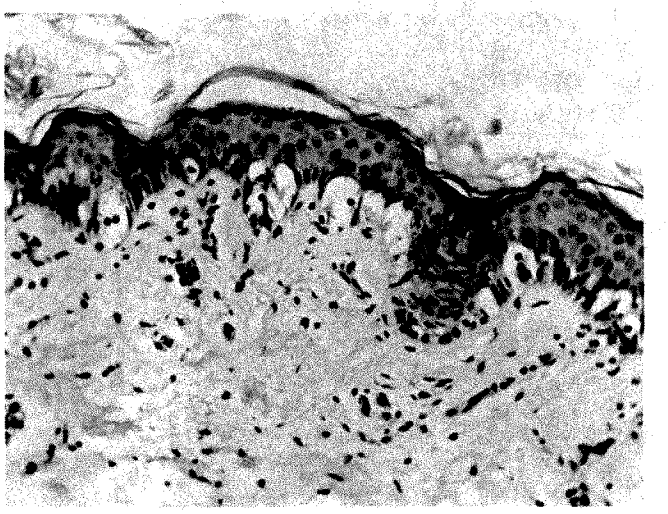

Fig 2.—Twenty-four-hour reaction. Considerable vacuolar degeneration of basal cells with dermo-epidermal separation. Dermis is edematous. (hematoxylin-eosin, original magnification ×260).

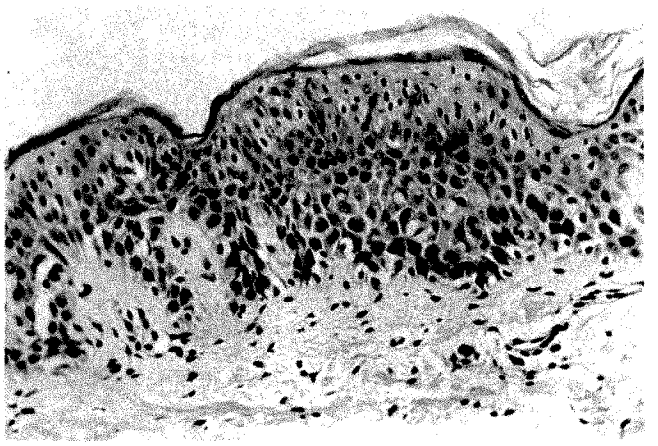

Fig 3.—Forty-eight-hour reaction. Spongiosis and vacuolar degeneration of keratinocytes, with necrosis of superficial cell layers (hematoxylin-eosin, original magnification ×260).

edema (Fig 1) to pronounced swelling and vacuolar degeneration of the basal cells with the formation of microvesicles (Fig 2). The latter were located above the PAS-positive basement membrane, resulting in subepidermal clefts. In the superficial layers, only a few foci of mild intracellular vacuolization were occasionally present. Sunburn cells were absent. The papillary dermis appeared diffusely edematous. The upper dermal vessels were dilated and surrounded by a sparse mononuclear infiltrate. By 48 hours, epidermal injury was even more pronounced, though dermal edema and vascular dilatation were somewhat lessened. In addition to vesiculation, there was extensive intracellular edema and almost all the keratinocytes appeared vacuolated (Fig 3). The cells in the superficial malpighian layers appeared swollen and their outlines hazy. Their cytoplasm was homogenized and stained less intensely. Most showed prominent perinuclear halos.

Wheal Reaction

Iontopheresis of Compound 48/80.—Only two of the seven subjects showed a diminished wheal and flare response in sites pretreated with compound 48/80. The burning sensation was not affected. The late reaction in the two subjects who showed a decreased immediate response was less pronounced.

Chlorpheniramine Maleate.—In two of ten subjects, prior injection of the antihistamine completely suppressed whealing, whereas in two others the wheals were diminished in size. Erythema and the flare-like response were also diminished but not abolished. The reaction was not altered in the other six subjects. The delayed response was also less pronounced in the four subjects in whom whealing was suppressed or diminished.

Corticosteroids

Neither topical nor oral steroids had any influence on the immediate or delayed phase of the phototoxic reaction in any of the nine subjects. The burning was unaffected.

Arterial Occlusion

In all six subjects, arterial occlusion completely suppressed the burning, erythema, and whealing. The delayed response was also completely abolished. Control sites over the opposite arms developed a brisk reaction. After the cuff was removed, a faint erythema developed in the irradiated site of only one subject.

COMMENT

The finding of variable activity among crude coal tars was not unexpected. Using chromatographic techniques, Gruber et al[5] found considerable differences among random samples of USP tars. Tar is an incred-

ibly complex mixture made up of literally thousands of substances. Samples will invariably vary with the source and mode of distillation. Chemical standardization is not a likelihood in the near future. The components that possess therapeutic activity are not even roughly known. At present, therapeutic efficacy is assessed by clinical testing in chronic dermatoses, such as psoriasis, an arduous and uncertain task. More reliable and simpler means of assay are needed. We have found that the antipsoriatic activity of various tars paralleled their phototoxic potentialities (unpublished observations). Crude coal tars were more effective than fractions derived therefrom. Vegetable and bituminous tars had no photosensitizing activity and were ineffective in psoriasis. These findings are similar to the observations made by Obermayer and Becker.[2] It seems possible, therefore, that a phototoxic assay could provide a means of predicting the efficacy of various tars in chronic dermatoses. Different tars and tar fractions could be quickly and easily appraised by a standard test of phototoxic capacity. However, more study is needed to substantiate our hypothesis that therapeutic activity and phototoxicity go hand in hand.

It should be pointed out that the reciprocal situation does not hold. Potent photosensitizers in tars such as anthracene and fluoranthene have no intrinsic activity when used alone in treating psoriasis (unpublished observations).

The phototoxic reaction can be clinically and histologically separated into two phases: an immediate urticarial reaction preceded by intense burning and erythema followed by a late phase characterized by considerable epidermal injury. The two phases blend into each other. Histamine liberation may play a role in mediating the immediate wheal and flare response. However, the results obtained in this study were not consistent enough to clarify this point. Further evaluation of this aspect of the immediate response is needed.

Prevention of the wheal and the late reaction by excluding arterial blood flow during irradiation suggests that the reaction is oxygen dependent (photodynamic). Other effects of arterial occlusion such as change in local pH or flow of mediators may also be important. Crow et al[6] also found that phototoxic reactions to anthracene were not influenced by antihistamines but could be blocked by arterial occlusion. Steroids had no effect on the course of the reaction. It should be noted that the microscopic signs of inflammation were minimal in the dermis, especially regarding cellular infiltration.

Studies by others provide some clue as to how phototoxic agents might incite an immediate wheal response. Anthracene, a photosensitizer in coal tar, has been shown to localize in lysosomes when incubated with macrophages in vitro.[9] Subsequent irradiation by UVA caused increased permeability of lysosomal membranes, with leakage of lytic enzymes and subsequent cell death. Anthracene can also damage cell membranes, as evidenced by hemolysis of irradiated RBCs.[10] Both types of membrane injury require oxygen. Allison et al[10] found that photosensitizers are readily taken up by lysosomes of mast cells and endothelial cells. The release of enzymes and other mediators from these different sources could explain the loss of fluid from vessels and account for the edema in the upper dermis.

Epstein[11] noted that immediate stinging and swelling will develop after coal tar photosensitization. This should be emphasized. Among the reactions to common contact photosensitizers, whealing is a singular characteristic of coal tar phototoxicity. The late reaction, however, is perhaps not very distinctive, showing mainly diffuse epidermal injury. The epidermal findings resemble those produced by other topical phototoxic agents such as chlorpromazine and bergamot oil.[11,12] Little is known about the histopathology of phototoxic reactions produced by different chemicals in human skin. The photosensitizing ingredients in tar include anthracene, fluoranthene, phenanthrene, benzpyrine, and acridine.[13,14] We found that anthracene, fluoranthene, and phenanthrene, in that order of phototoxic potency, produced responses indistinguishable from that produced by coal tar (unpublished observations).

Finally, mention should be made of the pigmentation that develops after resolution of the phototoxic reaction. This tends to be quite persistent. Hyperpigmentation is one of the most prominent features in the sun-exposed skin of pitch workers.[15] The phototoxic psoralens are also known to produce considerable stimulation of melanogenesis and as such have been successfully applied to the treatment of vitiligo. It is conceivable that coal tar might also prove beneficial in the treatment of that disease.

Papillary Eccrine Adenoma

David B. Rulon, MD, Elson B. Helwig, MD

• **We studied in 14 patients a distinctive eccrine sweat gland tumor that we have termed papillary eccrine adenoma. There was a majority of black patients, and the tumors were located most often on the distal extremities. Eleven patients were followed up for an average of 35 months after excision of the tumor. No tumor metastasized but one recurred, and since re-excision the patient has been followed up 30 months without further regrowth. Although previously regarded sometimes as malignant, the papillary eccrine adenoma is considered benign on the basis of our experience. Excision, with assurance from pathologic examination that the surgical margins are free of tumor, is the treatment of choice.**

Recognition of the neoplasm is based on the microscopic appearance of a pattern of structures resembling eccrine ducts, usually dilated, associated with intraluminal papillations.

(*Arch Dermatol* 113:596-598, 1977)

Fourteen examples of a distinctive neoplasm were found in the case records on file at the Armed Forces Institute of Pathology (AFIP). These cases were filed under sweat gland carcinoma or sweat gland adenoma. They were difficult to interpret and had been believed to occupy the gray zone separating benign and malignant neoplasms of the sweat glands. Since none was found to have metastasized, this lesion is provisionally considered benign. The diagnostic term of papillary eccrine adenoma is suggested.

METHODS

Special stains were carried out as described in the *Manual of Histologic Staining Methods of the Armed Forces Institute of Pathology*.[1]

RESULTS
Clinical Information and Diagnoses

The clinical information is summarized in the Table. Eight tumors (57%) were on the distal extremities, one on the wrist, and seven on the hands or feet. Eleven occurred in women and three in men, a ratio of about 4:1. Eight patients were black, one white, one American Indian, and in four the race was unknown.

The size of the tumors ranged from 0.5 to 2.0 cm in greatest diameter. The clinical appearance varied from red to brown and gray. None was painful, but two were tender. None was ulcerated. The lesions had been present for several months to 12 years before excision. The ages of the patients at the time of excision ranged from 9 to 69 years. Five were 20 years of age or younger, and six were older than 50.

Clinical diagnoses were made in five patients; these included rhinophyma, neuroma, fibroma, giant cell tumor of the tendon sheath, and sebaceous cyst.

The initial pathologic diagnosis was known in 12 patients. All lesions were considered to be neoplasms of sweat gland origin. One was regarded as a low-grade carcinoma by the contributor, and in three other cases the possibility of malignancy was noted in the diagnosis.

Clinical Data on 14 Cases of Papillary Eccrine Adenoma

Case No.	Age at Excision, yr	Sex	Race	Location	Duration	Size, cm	Length of Follow-up, mo	Additional Information
1	12	F	Black	Left middle finger	12 yr	2.0	99	Finger amputated
2	12	F	Black	Dorsum, left wrist	?	1.0	109	Re-excised
3	30	M	Black	Dorsum, left hand	Several mo	1.0	35	...
4	20	M	American Indian	Abdomen	11 mo	0.6	37	...
5	49	F	Black	Dorsum, foot	?	0.5	16	...
6	61	F	White	Nose	18 mo	1.5	30	Punch biopsy, then excision; surgery three previous times in 18 mo
7	62	F	Black	Lateral surface, hip	Several yr	0.5	26	...
8	63	F	?	Shoulder	?	0.7	None	...
9	14	F	Black	Foot	?	1.4	24	...

12	9	F	Black	Fifth toe	5 mo	0.9	12	...
13	52	M	Black	Upper thigh	Many yr	?	None	...
14	40	F	?	Leg	?	1.3	None	...

The AFIP consultant made an initial diagnosis of sweat gland carcinoma in one of the 14 cases and probable adenocarcinoma in another; the other 12 cases were interpreted as examples of sweat gland adenoma.

Of the 14 patients, 3 were lost to follow-up. Four were followed less than two years; four patients two to three years; one patient three to five years; and two patients for more than five years.

Eight of the 11 patients with follow-up information had no recurrence after excision. Two had additional surgical procedures (re-excision in one case and amputation of finger in the other) because a malignant condition was diagnosed or suspected on the basis of the histologic examination of the original material.

One lesion recurred. It was located on the nose of a 61-year-old white woman. The clinical diagnosis was rhinophyma. Surgical procedures were done 17, 12, and 6 months before two punch biopsy sections were taken, which were submitted for examination to AFIP. The extent of the first three excisions (or biopsies) is not known, and this material was not reviewed. The specimens from the punch biopsies were interpreted as atypical sweat gland adenoma (appendage carcinoma?), and a wider excision was done. The material from the punch biopsies showed mild nuclear pleomorphism and no mitotic figures in 50 high-power fields. Since the wide excision, no recurrence has occurred in the ensuing 30 months.

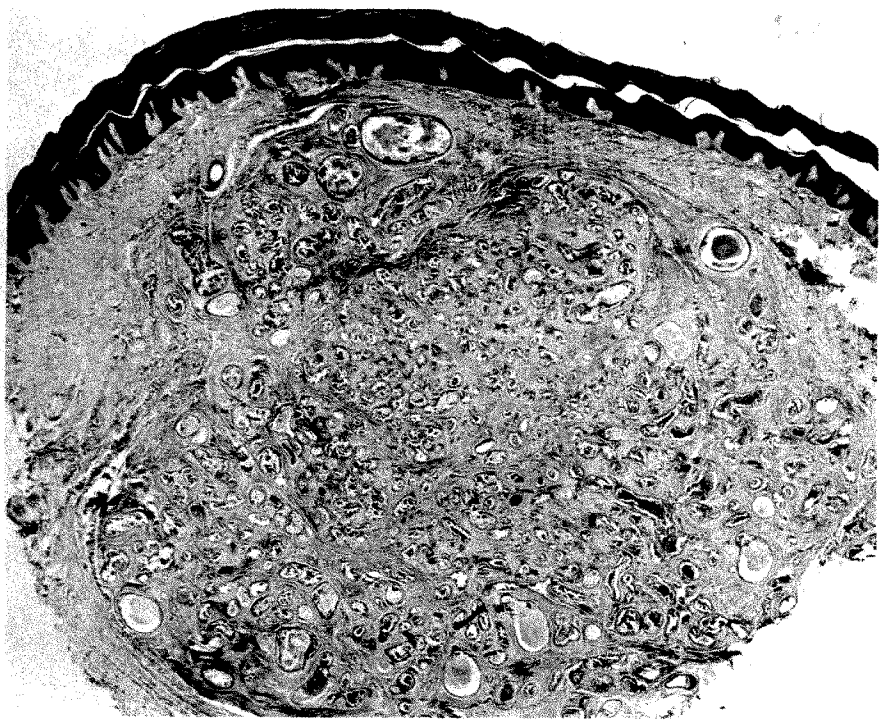

Fig 1.—Case 2: A disorganized fairly well circumscribed mass of ducts is localized in corium (hematoxylin-eosin, original magnification ×12).

Gross Features

The gross descriptions of the excised tissue were not distinctive. Poorly defined grayish-white areas of the dermis were noted, and in one instance the tissue was honeycombed with tiny cysts.

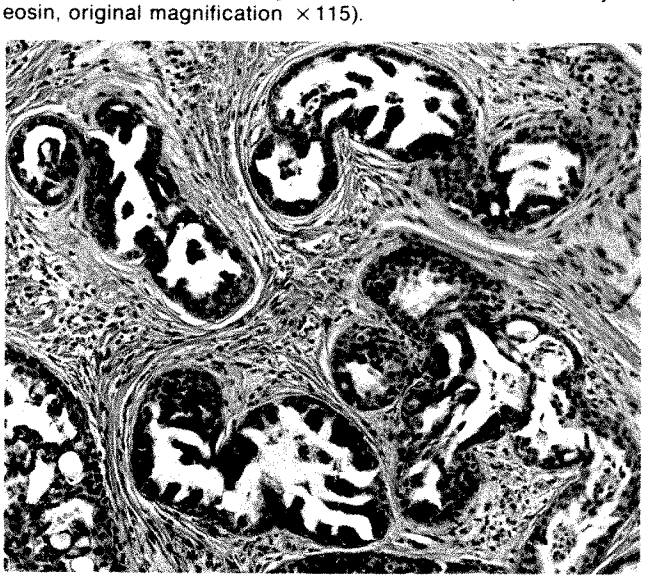
Microscopic Features

The distinctive microscopic appearance is characterized by the presence of dilated ducts of varying size (Fig 1). The ducts are lined by a double layer of uniform epithelial cells that form papillations projecting into the lumen and are surrounded by fibrous stroma (Fig 2-5). The ducts may contain amorphous eosinophilic material.

The epithelium lining the duct is, for the most part, two cells thick (Fig

Fig 2.—Case 4: Dilated ducts lined by double layer of epithelium with intraluminal epithelial papillations and eosinophilic secretion are surrounded by dense fibrous stroma (hematoxylin-eosin, original magnification ×115).

Fig 3.—Case 3: Pronounced and complex intraluminal papillations in large ducts surrounded by dense fibrous stroma (hematoxylin-eosin, original magnification ×115).



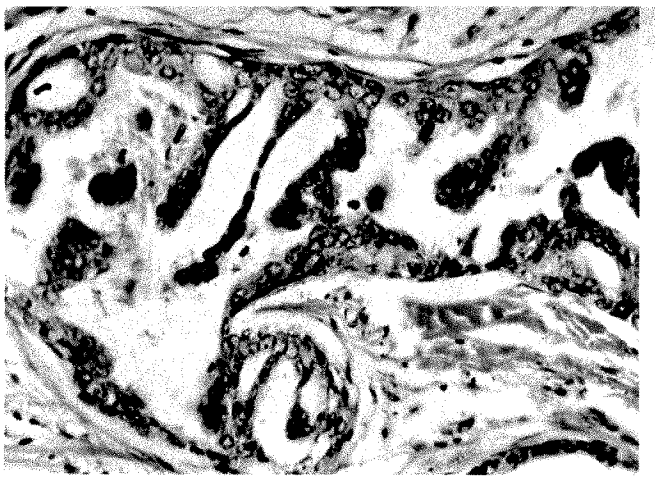


Fig 4.—Case 1: Intraluminal papillations are complex, and some have bullous tips (hematoxylin-eosin, original magnification ×285).

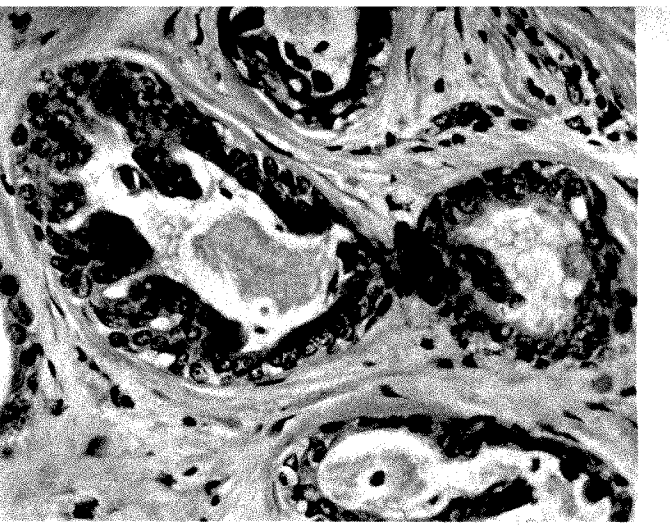

Fig 5.—Case 4: Cellular detail within duct. Nuclei are uniform and mitotic figures are absent (hematoxylin-eosin, original magnification ×285).

5). The outer layer of cells is cuboidal to flattened, and the inner layer may be flattened, cuboidal, or columnar. The cells in the inner layer may be crowded and pseudostratified, piling up into the lumen and forming complex patterns and papillations (Fig 3). The intraluminal papillations vary from two cells to several cells thick as the papillations become bulbous at the tip (Fig 4). The nuclei of the epithelial cells are uniform in size, oval to round, and have a thin rim, densely staining around the nuclear membrane, and often a prominent small eosinophilic or basophilic nucleolus (Fig 5). The cytoplasm of the cells is homogeneous and slightly eosinophilic. Mitotic figures are infrequent or absent.

The general outline of the lesion may either be circumscribed or have infiltrative margins. In one of the 14 cases the tumor infiltrated into the subcutaneous fat. The neoplasm has its own distinctive stroma replacing the normal pattern of dermal collagen. Some ducts are surrounded by a concentric arrangement of cellular fibrous tissue with fibrillar basophilic or amphophilic cytoplasm that often contains scattered lymphocytes. Other ducts are surrounded by dense sclerotic concentrically arranged hypocellular connective tissue. In the stroma investing some of the ducts are ill-defined small elongate cells suggesting myoepithelial cells. Large lymphocytic aggregates may be present in the fibrous stroma, and in two instances lymphoid follicles with reactive centers were noted. Epidermal ulceration and invasion of vascular or perineural spaces were absent. No tumors showed apocrine change, squamous differentiation, or clear cell areas.

Histochemical Findings

Tissue was available for preparation of special histochemical stains in seven of the 14 cases. The PAS stain, with and without prior diastase digestion, was done for the identification of glycogen and neutral mucosubstances. For identification of acid mucopolysaccharides, the Mowry modification of the Hale colloidal iron stain, with and without prior digestion by hyaluronidase, and the aldehyde-fuchsin stain at pH 1.0 and 1.7 were carried out.

Diastase-labile, PAS-positive granules interpreted as glycogen were present in the cytoplasm of epithelial cells lining the duct-like structures. In all seven examples, acid mucopolysaccharide was present along the luminal margins of the epithelial cells lining the ducts and within the ducts. This material stained with PAS after diastase digestion and with colloidal iron with and without hyaluronidase digestion. It did not stain with the aldehyde-fuchsin technique at either pH 1.0 or pH 1.7.

COMMENT

This peculiar tumor has not been previously recognized as a distinct category of sweat gland neoplasm. In four of our cases the contributor was concerned about malignant potential, and in one of these both the contributor and the AFIP consultant favored the diagnosis of sweat gland carcinoma. As yet the lesions on clinicopathologic correlation have not shown malignant potential. The lesion is uncommon. No similar cases were found in published reviews of sweat gland carcinoma.[2-8]

Surgical excision with assurance of complete removal by histologic examination of the surgical margins is considered the treatment of choice. The lesion is considered benign on the basis of available follow-up information.

Betamethasone Valerate Ointment Compared With Fluocinonide FAPG

Use in the Treatment of Psoriasis and Eczema

Dowling D. Munro, MD, FRCP; Trevor W. E. Robinson, MB, FRCP; Anthony W. P. du Vivier, MRCP; Dorothy M. France, MB, MRCP; Roger Clayton, MB, MRCP; Christopher G. Sparkes, PhD

• Betamethasone 0.1% as valerate in an ointment base and fluocinonide 0.05% in a fatty alcohol propylene glycol (FAPG) base have been compared in a double-blind trial of 76 patients with either eczema or psoriasis. The results show betamethasone valerate ointment to be significantly ($P < .05$) superior to fluocinonide FAPG in the treatment of both these skin conditions. In the light of publications from other studies on betamethasone valerate cream this trial indicates that the ointment base considerably increases the efficacy of betamethasone valerate.

(*Arch Dermatol* 113:599-601, 1977)

The intrinsic topical activity of corticosteroids, as predicted by the vasoconstrictor assay, and the influence of bases are both recognized as factors that affect the clinical efficacy of formulated preparations. Vasoconstrictor assays using alcoholic solutions of fluocinonide and betamethasone valerate have shown fluocinonide to be the more active.[1,2] Similar tests comparing fluocinonide in a fatty alcohol propylene glycol (FAPG) base with betamethasone valerate cream have shown fluocinonide FAPG to be marginally superior.[3] Some previous clinical trials, in which occlusive dressings were not used, have shown fluocinonide FAPG to be superior to betamethasone valerate cream in eczema[4-7] and in psoriasis.[4-6,8,9] Other trials have shown no difference between fluocinonide FAPG and betamethasone valerate formulated in a cream in eczema[5,10] or in psoriasis,[7,10] and one trial has shown a tendency for betamethasone valerate cream to be superior to fluocinonide FAPG in eczema.[11] Thus, although in some trials the number of patients studied was small and in some the results not statistically significant, it does appear that clinical experience parallels the results of the vasoconstriction tests in which the vehicle for betamethasone valerate is a cream.

Vasoconstriction tests comparing fluocinonide FAPG and betamethasone valerate in its ointment base have again shown fluocinonide FAPG to give marginally greater vasoconstriction values than betamethasone valerate ointment.[3] A similar comparison of betamethasone valerate cream with betamethasone ointment has shown the ointment to be superior to the cream.[12] The following report is the first comparing fluocinonide FAPG and betamethasone valerate ointment in the treatment of eczema and psoriasis.

METHODS

The severity of the cases reported represent those patients in the moderate to severe end of the disease spectrum for eczema and psoriasis who have failed to respond to general practitioner care and required hospital referral. Outpatients with clinically similar bilateral lesions were studied. The preparations were allocated at random to left or right sides and the identical looking tubes were labeled accordingly. Neither the clinician nor the patient was aware of their distribution. Patients were asked to treat their lesions twice daily. Assessment of the response was made at, or as near as possible to, seven days after the start of the trial and in all cases before 14 days. At each visit the following features of the lesions were assessed; erythema, scaling, induration, and exudation. An overall assessment of the relative improvment in these modalities was considered in making the final assessment; healed, improved, static, or worse. In similar previous trials this has been shown to give as good results as a more detailed way of recording the symptoms. In addition the clinician and patient were asked to record whether the response had been better on one side or the other or if no difference was detectable. It was recognized that the two bases were of a very different nature and were any to be left on the skin at the time of assessment such residues could give the clinician a clue as to the identity of the materials. To overcome this unlikely event patients were instructed not to apply the preparations on the day they visited their doctor. Clinicians were also asked to make their assessment before the patient had made any comments about the treatment.

As each patient completed the trial the observations were decoded by an independent observer. Preferences in favor of one or other preparation were plotted on a sequential analysis design[13] as they were decoded, thus permitting the trial to be stopped after treating the minimum number of patients. The boundary line was set to indicate a significance of 0.05%. Results showing that there had been an equal response to both preparations were defined as tied pairs and were not plotted.

The preparations used in this study were those commercially available in the United Kingdom, namely, fluocinonide 0.05% (Metosyn [England]; Lidex, comparable US product) and betamethasone valerate 0.1%

(Betnovate [England]; Valisone, comparable US product). There is no substantial difference between Metosyn and Lidex, but in 1973 Betnovate ointment base was changed, with 10% hydrogenated lanolin being replaced by 5% propylene glycol and it thus differs from Valisone ointment in this respect. The "new" and "old" Betnovate ointment bases have been compared in a trial similar to that described here and although the new formulation was more frequently chosen, the difference was not significant statistically.[14]

RESULTS

Seventy-six patients were included in the trial; the diagnosis and response to treatment is shown in Tables 1 and 2 and the Figure. The original protocol was for treatment with or without polythene occlusion, whichever was indicated on clinical grounds. However, as the trial continued it became clear that the occlusion was tending to obliterate differences between the two test substances, eg, in psoriasis of 14 patients without occlusion 11 showed a preference whereas of 15 patients with occlusion only 7 showed a preference. Therefore the nonocclusive cases were considered to reflect differences more accurately and this has been confirmed in other studies.[15] As a consequence only those patients treated without occlusion have been plotted sequentially. Also only those preferences recorded by the clinician have been plotted though these happened to coincide very closely with the patient preferences (see Table).

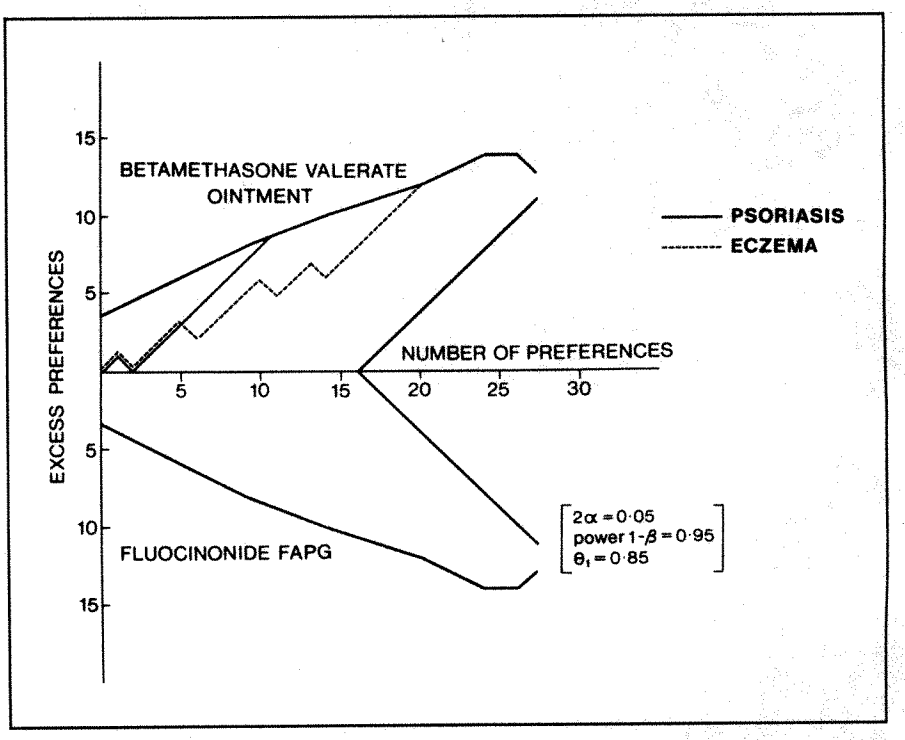
There were significantly (P .05) more preferences for betamethasone valerate ointment than there were for fluocinonide FAPG, in both eczema and psoriasis, and this level of significance was achieved in psoriasis with only half the number of patients required in the eczema study. This was mainly due to the fact that there were only 3 tied pairs in the psoriasis section and 13 in the eczema group.

In the majority of cases both sides were recorded as healed or improved. However one patient with psoriasis was improved after one week and was worse after two weeks on both sides and another, also with psoriasis, remained static on both sides for two weeks in spite of having polythene occlusion on both sides for the second week. All patients were asked if they experienced any sensation on application of the preparations. Twenty-four patients reported stinging or burning when applying fluocinonide FAPG and eight had similar symptoms with the betamethasone valerate ointment.

Numbers of Preferences* for Betamethasone Valerate and Fluocinonide

	Betamethasone Valerate	Fluocinonide	Equal	Total
	Without Occlusive Dressing			
Eczema	16 (16)	4 (5)	13 (12)	**33 (33)**
Psoriasis	10 (8)	1 (1)	3 (5)	**14 (14)**
	With Occlusive Dressing			
Eczema	2	3	9	**14**
Psoriasis	6	1	8	**15**

*Patient preference figures within parentheses.



Restricted sequential design that compares clinician's preference for one or another preparation.

COMMENT

In double-blind clinical trials improvement may be assessed either over a fixed period or until healing occurs. Clearly the two systems each have their advantages and in the present investigation a fixed period was used as this had been shown in other trials[15,16] to give good results while not increasing the duration and labor for the physician and patient, of the longer assessment period.

It has been shown that the use of propylene glycol in vehicles as a solvent for corticosteroids increases their activity both clinically and in vasoconstrictor tests, provided it is not present in excess of the optimal concentration.[17-19] Poulsen et al,[20] using fluocinolone acetonide and fluocinolone acetonide acetate (fluocinonide), have shown that maximal release for a given concentration of steroid is obtained from vehicles containing approximately the minimum amount of propylene glycol necessary to dissolve the steroid completely. They also observed that a base that is optimal for one corticosteroid is not necessarily suitable for another. Both fluocinonide in the FAPG base[21]

and betamethasone valerate in its ointment base[11] are in solution in propylene glycol. However, betamethasone valerate in its cream base is not in solution but is dispersed in microcrystalline form.[22] Thus it is not surprising that maximal activity of betamethasone valerate in vasoconstriction tests is seen in the ointment base.

Although the differences between the three preparations was very small, fluocinonide FAPG has been shown to cause more vasoconstriction than either of the betamethasone valerate preparations.[3] From this it might have been predicted that fluocinonide FAPG would prove to be clinically superior to both betamethasone valerate cream and ointment. Previous clinical studies have shown this to be true for the cream, but this trial points to the clinical superiority of betamethasone valerate ointment over fluocinonide FAPG. Thus the ointment base of betamethasone valerate would appear considerably to increase the activity of the steroid in clinical situations, this effect being particularly evident in the treatment of psoriasis.

Studies on the influence of vehicles on percutaneous absorption have shown that white soft paraffin has a substantial occlusive effect on the stratum corneum.[23] This occlusion leads to increased hydration of the epidermis with increased permeability allowing greater penetration of the corticosteroid. In addition it has been found that occlusion with polyethylene in humans reduces the epidermal hyperproliferation found in psoriatic lesions.[24] Recently Tree and Marks[25] have shown that various bases (without containing any corticosteroid) have an antimitotic effect when applied under occlusive dressings to the backs of mice. They found that white soft paraffin was the most effective of the bases tested and they suggested that the effect may have been due to the greasy nature of the base slowing the rate of desquamation, which in turn might affect cell production. Thus the results seen in the study reported here may also be due in part to an intrinsic effect of the base.

These results possibly signify that the FAPG base lacks the occlusiveness and emolliency of traditional greasy ointments and does not therefore have the properties of both a cream and an ointment as has been claimed previously.[6] The increased irritancy seen with the FAPG base would indicate that lack of patient acceptability might limit its use. Hence, it would seem that manipulation of the physical environment can have a profound effect on the treatment of skin diseases and it may be that the triple effect of optimal solubility of the steroid and the use of a base that provides both occlusivity and a reduction in mitotic activity are factors necessary to get the maximal effect from a given topically active corticosteroid.

The differences in results between this trial and others suggest the relevancy of further inquiry into the influence of vehicles on the clinical efficacy of topically active steroids.

A Cutaneous Marker in the Hunter Syndrome

A Report of Four Cases

Stephen D. Prystowsky, MD; Irene H. Maumenee, MD;
Robert G. Freeman, MD; James H. Herndon, Jr, MD; Mary Jo Harrod, PhD

• A report of four patients and review of the literature suggest that a cutaneous marker exists for the Hunter syndrome. All previously described patients with this eruption have been males with clear corneas. The distinctive lesions consist of firm ivory-white papules and nodules that may coalesce to form ridges or a reticular pattern. The papules are usually seen in symmetrical areas between the angles of the scapulas and posterior axillary lines, the pectoral regions, the nape of the neck and/or on the lateral aspects of the upper arms and thighs. These lesions are seen in both allelic forms and cannot be used to separate a benign from a rapid course.

(*Arch Dermatol* 113:602-605, 1977)

In 1917 Hunter[1] first described the syndrome that was to bear his name when he described two brothers with severe shortness of stature, stiff joints, claw-like hands, deafness, hepatosplenomegaly, cardiomegaly, unusual facies, and a peculiar nodular skin lesion over the scapulas. Patients with similar findings but with additional features of pronounced dwarfism, corneal clouding, gibbus, and mental retardation were described in 1919 by Hurler on the suggestion of Dr. Pfaundler[2]; no skin lesions were noted. Additional disorders with similar phenotypes were added by other authors.[3]

In 1946 Nja[4] recognized that certain families with gargoylism could be distinguished. An X-linked form of inheritance was inferred from reports of families in which all affected members were males. No corneal clouding occurred in these patients. Other forms of gargoylism occurred in siblings of both sexes in equal proportions, did not occur in successive generations, and occurred more frequently to consanguineous unions, suggestive of an autosomal recessive mode of inheritance. McKusick introduced the first classification of the mucopolysaccharidoses in 1960.[5] The Hunter syndrome, mucopolysaccharidosis II, is due to a deficiency of sulfoiduronate sulfatase.[6]

However, at least two forms of the Hunter syndrome have been recognized clinically: a severe form with mental retardation and early death and a mild form, in which mental function is normal and which is compatible with survival to adult life. Intermediate forms probably exist. It was the mild form that Hunter originally described. No other clinical differences consistently distinguish the two types; each seems to segregate uniformly in affected families. Biochemical investigation of the two forms has indicated that they lack the same corrective factor. Characterization of this group of degradative enzymes has hardly begun, however, and it seems possible that the two (or more) forms of the disorder may depend upon separate classes of instabilities in the same enzyme molecule or defects in separate isoenzymes with different distributions in tissue. In genetic terms, these possibilities may reflect abnormal genes that behave as alleles at the same locus on the X-chromosome.[7,8]

The purpose of these case reports is to define further the distinctive cutaneous lesion of the Hunter syndrome[9] and to examine previous reports to

document the specific character of this finding.

REPORT OF CASES

CASE 1.—An 8-year-old white boy was the product of a normal pregnancy and delivery. Psychometric evaluation placed his developmental age at 2 years. He had severe physical and mental retardation and frequent upper respiratory infections. The cause of his retardation had not been established until characteristic dermal nodules and ridges were noted by a consultant dermatologist. A family history disclosed none of 43 close relatives affected.

Firm, ivory-white, 2- to 10-mm papules and nodules, which coalesced to form ridges in a reticular pattern, were seen in symmetrical areas between the angles of the scapulas and posterior axillary lines (Fig 1 and 2). Similar lesions were present on the upper arms, lateral aspects of the thighs, and pectoral regions. The lesions first appeared on the arms and back prior to age 1. Lesions appeared in the pectoral region at age 6 (Fig 3). The nodules have enlarged with age and none have disappeared. Additional pertinent physical findings included generalized downy hypertrichosis, broad hands with stubby fingers resulting in a claw-like contracture of the hands, coarse facial features, hepatosplenomegaly, stiff joints, and clear corneas. Hearing difficulty has recently been noted.

A karyotype showed the chromosome complement of a normal male (46, XY). The urinary glucosaminoglycan levels were elevated to 14 mg/100 ml. Roentgenograms showed broad ribs, short clavicles, no lumbar gibbus, a mild flexion deformity of the fingers, thickened calvaria, rounded scapulae, and proximal tapering of the metacarpal bones characteristic of the Hunter syndrome.

Histopathology of the papules revealed foci of irregularly organized collagen bundles separated by interfibriller material. Sections stained with toluidine blue contained deposits of metachromatic material. The epidermis and appendages ap-

peared normal.

CASE 2.—A 6-year-old white boy is the third child in the family to have Hunter syndrome. Two older brothers were affected and died at 7 and 12 years, respectively. Shortly after birth, the parents noted that the patient was "blockier" than other babies. He has severe mental and physical retardation.

Pale, 3- to 4-mm papules and nodules are present in symmetrical areas on the upper pectoral regions and scapular areas. The corneas are clear. Other pertinent physical findings include short stature, coarse facies, large head, saddle-shaped nose, thick lips, large tongue, deformed teeth, hepatomegaly, and hirsutism.

Severely elevated glucosaminoglycan levels were present in the patient's blood and urine samples. The pathologic findings were identical to those of case 1, and are being reported separately.

CASE 3.—A 13-year-old white boy with the Hunter syndrome was first referred at age 10 years with the diagnosis of Sanfilippo syndrome. He was a big baby at birth, and grew rapidly in the first years. He did develop an umbilical hernia during his first year of life. His early development measurements were reached within the normal limits. He developed speech normally and, by age 4 years, entered nursery school. At the end of that school year, the mother was told that the boy was somewhat slow and clumsy. Examination of the skin at age 5 years showed pebbling over both pectoral and scapular areas and over the thighs. There were flexion contractions over many joints. The liver was about 5 cm below the right costal margin and the spleen about 2.5 to 3 cm below the left costal margin. He still appeared of normal intelligence and was active and cooperative. The diagnosis of "mild Hurler disease" was made. A year later an IQ of 62 was established. His general features and the organomegaly became more prominent. At a slow rate, he acquired new skills until 1970, when he started regressing. In 1971 he had lost almost all of his vocabulary; also, at about that age he stopped growing. He has one normal sister.

On physical examination at age 10 years, he had coarse facial features (Fig 4), clear corneas, thickened earlobes, hepatosplenomegaly, and umbilical hernia, as well as joint limitations involving primarily the upper extremities (Fig 5). On dermatologic examination he was mildly hirsute over his trunk and extremities. His scalp hair and eyebrows were coarse. He had skin pebbling over the nape of the neck, the scapular areas bilaterally, and the pectoralis muscles. In 1972 he was given a trial of plasma infusions for one year; there was no improvement except for substantial diminution of the cutaneous lesions. The lesions were still present in January 1975. Iduronide sulfate sulfatase deficiency had been documented in this boy.

CASE 4.—An 8-year-old white boy was above the 97th percentile for height and weight until age 2½. His early development measurements were delayed. He was hyperactive and had frequent respiratory infections and asthmatic episodes during the first years. He has three normal sisters.

On physical examination at age 2½ years, he was mildly hirsute over his back and extremities. His scalp hair was sparse but coarse. He did not have the characteristic pebbles over the chest and back. The child continued to be followed up in the Moore Clinic, and from age 5 to 7 years was infused with plasma without significant sustained improvement. In 1974 he developed for the first time the characteristic skin pebbles over his scapula area only. On re-evaluation in 1975, the classical features of the Hunter syndrome progressed. However, he continued to have an IQ of 80, the level of low normal intelligence. Iduronide sulfate sulfatase deficiency, diagnostic for the Hunter syndrome, was found. The skin lesions had spontaneously improved during the previous year and were barely detectable in May 1975.

COMMENT

The Table provides details of our and the previously reported cases with the characteristic cutaneous lesions of the Hunter syndrome. Nine patients

had lesions whose descriptions closely resemble those of the present cases. From these descriptions one can draw a picture of the distinctive lesions of the Hunter syndrome: they consist of firm, flesh-colored to ivory-white papules and nodules that often coalesce to form ridges or a reticular pattern and occur in symmetrical areas between the angles of the scapulas and posterior axillary lines, the pectoral regions, the nape of the neck and/or the lateral aspects of the upper arms and thighs. They appear before age 10, and can spontaneously disappear. Reference to previous reports[1,10-15] and to experience of clinical geneticists[6] suggests that this eruption is probably pathognomonic for the Hunter syndrome. The available data show the following: (1) all reported cases with this lesion were in males; (2) all such patients had clear corneas; and (3) all affected siblings of index cases were male. Since the Hunter syndrome is the only X-linked mucopolysaccharidosis recognized so far, and nearly all patients with the otherwise similar but autosomally transmitted Hurler syndrome have cloudy corneas, the exclusively male occurrence of the characteristic skin lesion and its uniform accompaniment of clear corneas strongly supports our contention that the eruption indicates a diagnosis of the Hunter syndrome. The Sanfilippo syndrome is the only other mucopolysaccharidosis in which there is a clear cornea. The best way to provide conclusive proof for the association would be to assay for the specific enzyme deficiency in all cases. These tests are available only at a few research centers. Moreover, most authorities agree that neither total nor fractionated urinary mucopolysaccharide determinations can differentiate the Hurler syndrome from the Hunter syndrome: chondroitin sulfate B (dermatan sulfate) and heparitin (heparin) sulfate are excreted excessively in both.[8] In short, recognition of the cutaneous marker (when present) may be helpful in making a diagnosis with important implications for the patient's future development, as well as for genetic counseling of the family. We interpret the concordance in 13 reports (including the present 4) as adequate indirect evidence for the association with the Hunter syndrome.

McKusick has recently reclassified the genetic mycopolysaccharidoses,[8] taking into account the two presumably allelic forms of the Hunter syndrome. Unfortunately, the cutaneous lesions of the Hunter syndrome are seen in both allelic forms and cannot be used to differentiate a benign from a rapid course. Review of the cases shown in the Table demonstrate that six patients had the benign form, five had the severe form, one had an intermediate form, and in one previous report the data were insufficient to determine the allelic type.

Although the cutaneous abnormality discussed is a reliable marker, the majority of cases reported with the Hunter syndrome do not mention this finding. A review of recent cases followed up at the Johns Hopkins Hospital showed that only 2 of 11 patients with the Hunter syndrome, ranging in age from 18 months to 31 years, had the cutaneous marker.

Only one of four pedigrees with more than one affected member reported skin lesions in more than one patient. This variability of expression suggests that unknown secondary factors affect the appearance of the cutaneous marker. It is also unknown why no patients with any of the other mucopolysaccharidoses have a similar eruption.

This study was supported in part by grants 5 P01 GM 19489, 5 T01 GM 00795, and 1 M01 RR00722 from the National Institutes of Health; grant CRBS-322 from the National Foundation–March of Dimes; by the Bob Hope Fight for Sight grant, Fight for Sight, Inc, New York City; and a grant from the Syntex Corp, Palo Alto, Calif. Psychogenic Purpura

William W. Stocker, MD; O. Ross McIntyre, MD; William E. Clendenning, MD

• Two young women had painful ecchymoses of their extremities. In one, this purpuric syndrome followed a chronic course and resulted in severe joint disability. In the other woman, the problem was transient and relatively benign. Emotional factors in their disease were of major importance. No abnormalities of hemostasis or immune function were found. These cases demonstrate the many problems encountered in the diagnosis and management of such patients.
(*Arch Dermatol* 113:606-609, 1977)

Hemorrhage into the skin leading to painful ecchymoses and disability is a well-recognized syndrome that occurs predominantly in women. Three different proposed mechanisms have been emphasized by the names suggested for this syndrome: autoerythrocyte sensitization,[1] psychogenic purpura,[2-4] and factitial purpura.[5,6]

In 1955 Gardner and Diamond[1] reported a painful bleeding syndrome in four women in whom no coagulopathy could be found. They demonstrated skin reactions to the patients' own erythrocytes and postulated an autoimmune mechanism whereby trauma (either accidental or surgical) leads to sensitization to erythrocytes. Then subsequent minimal daily trauma was thought to result in an allergic reaction to extravasated RBCs. This led to the designation "autoerythrocyte sensitization" syndrome.

The second major idea regarding these patients is that psychogenic factors are paramount in the pathogenesis. Ratnoff and Agle[2] and Agle et al[3] did extensive studies on 28 women with this syndrome. They proposed that the hemorrhage into the skin represents a conversion symptom that results from emotional stress in women who have strong masochistic and hysterical character traits. They postulated that the conversion reaction might be mediated through the kinin system and suggested that the syndrome be called "psychogenic purpura."[4]

Self-infliction of the purpuric lesions is the third mechanism that has been discussed in the literature. Cases similar to those reported earlier have been proved to be factitial.[5,6] The similar personalities of these patients and patients with factitial diseases indirectly support this mechanism.[7] "Factitial purpura" is the term used to describe these patients.

Scattered reports of abnormalities in platelet function have been reported.[8] However, in the vast majority of these patients, most of whom have been extensively studied, no abnormalities of hemostasis or immune function have been demonstrated.

The purpose of this article is to review this complex entity and to present the case reports of two disturbed women who had similar initial complaints but whose illnesses differed greatly in duration and in morbidity.

REPORT OF CASES

Case 1.—A 21-year-old woman was first seen at her local hospital in March 1974 for a soft tissue mass over her distal right ulna that had developed from a painful bruise first noted in January 1974. There was a history of striking the area on a car door. The mass was excised and showed benign hypertrophic fibrous tissue. This sequence of events, involving the same area, was repeated in May 1974. The soft tissue mass was reexcised with the same tissue diagnosis.

She was hospitalized for the third time in June 1974 for severe vomiting at which time hysterical behavior was observed. A diagnosis of psychogenic vomiting was made.

During the summer of 1974 the right wrist bruise and swelling recurred again. She was seen at a second hospital in the fall where the mass and the distal head of the right ulna were excised to allow proper movement of the wrist.

She returned to the original hospital in December 1974 with swelling over the left wrist that had developed from a painful, bruised area during the preceding eight weeks. The mass and distal head of the left ulna were excised and a cast was applied.

In January 1975, further bruises of the left knee, left ankle, and right wrist developed. Results from clotting studies were normal. The diagnosis of autoerythrocyte sensitization was considered; skin tests to her own RBCs were negative. She was then referred to our hospital for further evaluation.

Physical Examination and Laboratory

Accepted for publication June 30, 1976.

Fig 1.—Painful ecchymosis of left knee in case 1. Hemarthrosis was demonstrated.

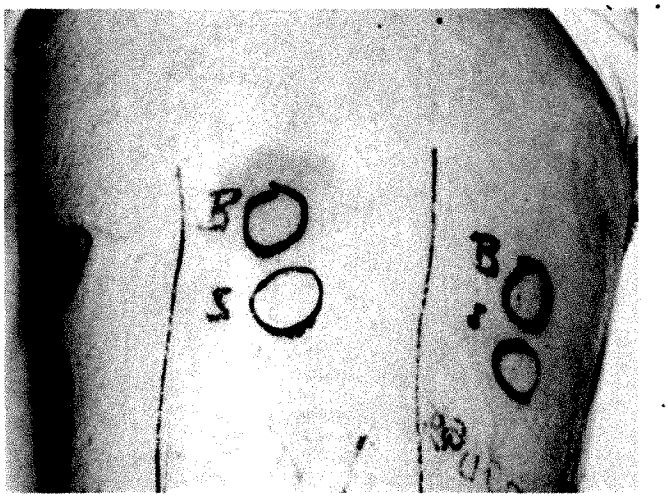

Fig 2.—Case 1: skin test site at 48 hours. B sites were injection sites of blood. S sites were sterile saline injections. Patient thought that only middle B site was her own blood.

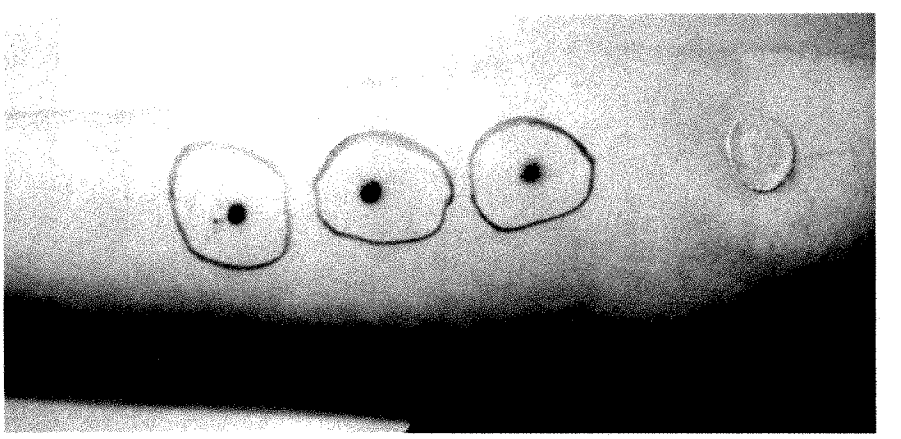
Fig 3.—Painful ecchymoses of right upper arm suggesting finger and thumb imprints.

Fig 4.—Case 2: skin test sites immediately after injection of patient's blood.



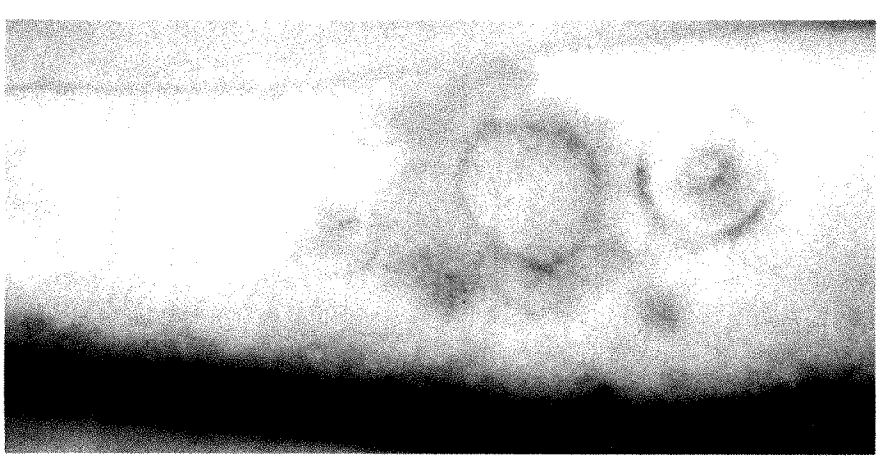


Fig 5.—Case 2: skin test sites at 48 hours showing extensive ecchymosis only of center site.

Studies.—Results of the physical examination were normal except for multiple, painful ecchymoses of the extremities (Fig 1). Results from an extensive clotting and connective tissue workup were normal. For the clotting studies results from the following tests were normal: CBC, platelet count, recalcification time, bleeding time, fibrinogen titer, fibrin split products, thrombin time, special clotting studies—clot retraction, platelet factor 3, platelet aggregation

studies, platelet size, glass-plastic ratio, activated partial thromboplastin time (APTT)-auto APTT, Hyland APTT, factor II, VIII, IX, XI, and XII assays—urea clot solubility, and monochloracetic acid clot solubility. The other tests performed, the results of which were normal, are as follows: protein electrophoresis, antinuclear antibody, rheumatoid factor, antistreptolysin O (titer), VDRL, cold agglutinins, antiglobulin screen, Cl esterase inhibitor, C3 complement, and sedimentation rate.

Skin Test.—Skin tests to her own erythrocytes were performed as will be described. A "positive" test developed as shown in Fig 2. A biopsy specimen from this site revealed only hemorrhage. There was no inflammation or vasculitis.

Hospital Course.—The pain and bleeding around the left knee became more severe to the point where she could not bend it or bear weight. She was taken to the operating room where, under general anesthesia, 5 ml of blood was aspirated from the joint space and the knee was easily manipulated. A long leg cast was applied. She refused inpatient psychiatric care and was discharged.

Subsequently, she had two admissions for bleeding around her left knee and right elbow. After the application of casts, she improved and new lesions did not develop under the cast. When the casts were removed, new lesions developed in the same areas within one to three days. She was able to predict the site and onset of new lesions.

In April 1975, she agreed to admission to the psychiatric unit for evaluation. Her psychiatric history was of importance in several respects. During the past five years, her mother had undergone treatment for laryngeal cancer. Six months before the onset of her symptoms, her brother had been severely beaten by an uncle. Also before the onset she had had morbid nightmares about death and injury to her family. She related the onset of her first bruising as coinciding with the return of her fiancé from Viet Nam. Hysterical symptoms in 1974 had led to neurologic and cardiac evaluation that included coronary arteriograms.

During her psychiatric admission, two additional casts were removed from extremities and no new lesions were seen. The next day after the cast removal a medical student, walking into her room, heard a regular thumping noise from her bathroom over the sound of running water. She was not confronted. The same day pain and swelling developed around her left knee. This progressed to ecchymosis during the next two days. She refused audio or visual monitoring and at her strong demand was discharged and has not returned.

Throughout her course, she showed relative indifference to her serious crippling problems and a martyr-like acceptance of herself as a chronic invalid. She has postponed her wedding date.

CASE 2.—The patient was also a 21-year-old woman who came to the hematology clinic of this medical center in February 1970 complaining of tender bruises of her chin, upper arms, and upper legs of two to three days' duration. Her occupation was as a licensed practical nurse. She was engaged and planning to be married in August 1970. There was a history of a recent nose bleed, but no other hemorrhagic episodes. On examination, some of the ecchymoses were in a pattern that suggested finger marks (Fig 3).

Results of the following laboratory tests were normal: CBC, platelet count, bleeding time, clot retraction, prothrombin time, partial thromboplastin time, thrombin time, and recalcification time.

Skin tests to her erythrocytes were performed (Fig 4) as will be described. A positive skin test developed as shown in Figure 5.

The test and the implication that this was a self-induced problem related to emotional stress was explained to her. She then admitted to being afraid that she was pregnant. She was seen by a psychiatrist as an outpatient in March 1970. The bruising symptoms have not recurred over the subsequent six years.

Her history and present findings are, however, important. At age 12 she had a laparotomy for suspected appendicitis; a normal appendix was found. From 1967 to 1976 she has undergone multiple urologic procedures for evaluation of severe flank pain. She underwent cystoscopy and meatal dilitation several times as a teenager. In 1970 a calcium oxalate stone was passed. Because of her persistent symptoms, but in spite of normal x-ray film studies, she had an extensive metabolic workup that included normal results from a neck exploration for parathyroid adenoma. She continued to complain frequently to several physicians of severe flank pain. Her urologists are convinced that many of her symptoms are hysterical, although she has passed two calcium stones in the past.

She was married in August 1970. She took an overdose of a mixture of propoxyphene hydrochloride, aspirin, phenacetin, and caffeine (Darvon Compound) in November 1970, was admitted to intensive care, and recovered without complications. A history of emotional deprivation as a child has been obtained.

Comparison of Features of Psychogenic Purpura With the Cases Presented

Common Features of Psychogenic Purpura[2]	Case 1	Case 2
Most frequent in women aged 14-40 yr	Yes	Yes
Ecchymoses occur predominantly on the extremities	Yes	Yes
Severe emotional turmoil preceding symptoms	Yes	Yes
Multiple somatic complaints without objective findings	Yes	Yes
Subjective prodrome before new lesions	Yes	Uncertain
History of multiple surgical procedures	Yes	Yes
Hysterical and masochistic character traits	Yes	Yes
Ability to manipulate lesions in some patients under hypnosis[3]	Not tested	Not tested
Variable results of skin tests to patient's RBCs	Yes	Tested only once
A biopsy of lesions shows absent or minimal findings	Yes	Not done

METHODS FOR SKIN TESTS

Before the test was done, the physician explained to the patient that her bleeding problem might be due to a reaction or sensitivity to her own blood. She was told that only the middle of the three test sites was her own blood, and that the other two test sites were cross matched donor blood. She was told that a positive test is the development of a bruise in the center site.

Six milliliters of the patient's blood was drawn into a sterile, heparinized tube. In another room away from the patient, three 0.1-ml aliquots of this blood was drawn into three tuberculin syringes. These 3 aliquots were then injected intradermally into a reachable area (Fig 4). A positive test was the development of a painful ecchymosis during the subsequent 24 to 48 hours in the central site only (Fig 2 and 5).

COMMENT

These cases illustrate many features and questions regarding the entity that is perhaps best designated

as psychogenic purpura. First is the question of autoerythrocyte sensitization. The patient in case 1 showed variable results when tested with her own RBCs. Specifically, the initial tests were negative and the subsequent ones were positive only in areas she was told were her own RBCs. A biopsy specimen from a positive skin test site showed no evidence of a vasculitis or inflammation. Both patients underwent several surgical procedures without hemostasis problems. These features have been emphasized by Ratnoff and Agle[2] in their patients with psychogenic purpura. In case 1 and that of Levin et al's,[6] initial skin tests were negative and later ones were positive. The failure to consistently demonstrate sensitivity to injected RBCs, the absence of inflammation in the skin of test sites, and the ability of these patients to undergo repeated surgery without hemorrhagic or immune castastrophies all suggest that the autoerythrocyte sensitization hypothesis is untenable.

The term psychogenic purpura has been used to imply purpura caused by a true conversion reaction.[2-4] The Table gives many of the common features of these patients and shows that the present cases "fit" this profile quite well, particularly the psychiatric and personality profiles. Levin et al's[6] case report was of a 16-year-old girl with a similar background. Her lesions were proved to be factitial by direct observation. It is reasonable to speculate that the purpura in all of these cases has a similar mechanism, but it is impossible to resolve this hypothesis because of the difficulty in completely disproving factitial causation and proving a mechanism that results from a conversion reaction.

The present case reports show some of the criteria that can be used to help distinguish a factitial mechanism from a conversion reaction. A major factitial component seems reasonably established for the patient in case 1 for the following reasons: (1) new ecchymoses never developed under casts and old ecchymoses resolved under casts; (2) lesions regularly developed on extremities one to three days after the removal of a cast from the extremity; (3) suspicious "banging" noises that were heard in her bathroom were followed by new bruises; and (4) she refused audio or visual monitors in her room. The "finger" pattern of the bruises on the patient in case 2 was strong objective evidence for self-infliction.

The usefulness of skin tests to the patient's RBCs in this syndrome has been controversial. As just discussed, true sensitization to erythrocytes has never been shown to be the mechanism of this syndrome, but skin tests may be helpful in other ways. Painful ecchymoses developed in both of these women at sites that they were told were their own RBCs and not in sites that they thought were donor's blood. Besides confirming the absence of autoerythrocyte sensitization, these results cannot be explained by any known coagulopathy and obviate the need for an extensive clotting and immune evaluation. Case 2 shows the potential benefit of performing this test early and recommending early intervention by a psychiatrist.

The performance of this test requires several conditions. First, the physician must explain the test and suggest that the patient will react only to the site he is told are his own RBCs. Second, the patient must choose to inflict the positive test at the site. Third, the patient must be able to reach the test site. A positive result is consistent with a factitial cause but does not rule out a true conversion reaction. A positive reaction in a reachable area, and a negative test in an unreachable area would be further evidence for a factitial mechanism. This approach was used by Levin et al[6] in their case that was proved to be factitial by direct observation. A negative test in all areas does not rule out either a factitial cause or a conversion reaction.

Several points require emphasis. Patients with factitial purpura seem to have personality traits and emotional backgrounds similar to those of patients described with psychogenic purpura. If direct observation of a patient is not possible, factitial causes may be implied by the improvement of old lesions and failure of new lesions to develop under casts; by development of positive skin tests to the patient's own RBCs only in reachable sites that the patient has been told are his own RBCs; and by the morphology or pattern of the skin lesions. Extensive laboratory evaluation, hospital admissions, and surgical procedures potentially can be avoided by early recognition of the emotional and personality factors and by early application of these techniques.

The term psychogenic purpura should be broadened to include both purpura resulting from a conversion reaction and purpura resulting from self-inflicted injury since these patients share many common features and frequently are difficult to separate. All such patients are emotionally disturbed and in need of psychiatric care.

Lee R. Zacharski, MD, of the White River Junction Veterans Administration Hospital, White River Junction, Vt, performed the special clotting studies.

Bullous Pemphigoid Responding to Sulfapyridine and the Sulfones

John R. Person, MD, Roy S. Rogers III, MD

• **Since 1968, a total of 84 patients with bullous pemphigoid have been seen at the Mayo Clinic. Of these, 41 were given a trial of sulfapyridine or dapsone, and six showed a significant response. In five patients, the condition was controlled completely. All responsive patients showed indirect and direct immunofluorescent tests indistinguishable from typical bullous pemphigoid. The patients, however, were somewhat younger (mean 54 years) than others having pemphigoid; and in two patients, biopsy specimens showed a reversal of the usual eosinophilic predominance over neutrophils. Three of the six patients were also diabetic.**

(*Arch Dermatol* 113:610-615, 1977)

Bullous pemphigoid is not generally considered to be a sulfa-responsive dermatosis. Lever,[1] in his second monograph on pemphigus and pemphigoid, stated, "The sulfones and sulfapyridine are of little or no value in the treatment of bullous pemphigoid. Only an exceptional patient with bullous pemphigoid responds to treatment with these drugs." Indeed, in the past, a bullous dermatosis responsive to sulfas and sulfones was considered by some to be diagnostic of dermatitis herpetiformis.[2-4] However, in 1953, Rook and Waddington[5] reported using sulfapyridine to treat 17 of 38 patients with bullous pemphigoid. The condition of four of these 17 was controlled, that of seven improved, and that of six remained uninfluenced or was aggravated by the medication. Little has been written regarding this mode of therapy for pemphigoid since that time.

In 1972, Honeyman et al[6] described five patients who shared clinical, histopathologic, and immunofluorescent criteria for both dermatitis herpetiformis and bullous pemphigoid. Although the authors failed to mention specifically which patients responded to sulfapyridine or dapsone at a given stage in their clinical course, we assume that the condition of at least some of their patients was best classified as sulfa-responsive bullous pemphigoid.

Before 1965, at least four cases were described in which the patient had an atypical bullous dermatosis and responded favorably to treatment with sulfonamides. The pathologic findings in these cases showed intraepidermal bullae with variable amounts of acantholysis suggestive of pemphigus vulgaris.[7-9] Emmerson and Wilson-Jones[10] described seven cases of pemphigus in which early biopsies showed eosinophilic spongiosis without acantholysis. In three of their cases, the lesions initially resembled dermatitis herpetiformis clinically but did not respond to dapsone. More recently, four cases of both histologically and immunologically confirmed pemphigus with clinical features of dermatitis herpetiformis have been described. The condition in all patients was completely controlled by sulfapyridine or dapsone.[11-13]

We would like to report six cases of immunologically typical bullous pemphigoid in which the patient responded to therapy with sulfapyridine or dapsone.

PATIENTS

Between 1968 and 1975, 84 patients with bullous pemphigoid were seen at the Mayo Clinic. Of these, 41 had trials of sulfapyridine or dapsone although not all of the trials resulted in therapeutic blood levels of sulfapyridine. Three patients were given sulfapyridine only in conjunction with corticosteroids and three had only mild or transient responses. Six patients showed a significant response (Tables 1 and 2), and these cases are presented.

REPORT OF CASES

CASE 1.—A 65-year-old man first came to the Mayo Clinic in April 1968, with a five-year history of pruritic, papular, excoriated scalp lesions. Two years before this, he had had a brief episode of conjunctivitis and eyelid erosions, which cleared with the use of eyedrops containing polymyxin B, neomycin, and hydrocortisone (Cortisporin); at that time, nonpainful dysphagia and oral erosions also developed and had persisted. Thirteen months previously, bullae and erosions of the groin, genitalia, and buttocks, which by history demonstrated a positive Nickolsky sign, had begun. He had been hospitalized twice for this problem and had been taking 30 mg of prednisone daily for the preceding year. He also related a ten-year history of diabetes mellitus controlled by sulfonylureas and a one-month history of progressive, nonradiating low back pain.

On examination, crusted erythematous plaques were noted on the elbows, buttocks, and perianal and pretibial regions as well as numerous, discrete, 1-cm crusted lesions on the scalp. Erythematous erosions were noted on the palate and left buccal mucosa; in addition, he had a 5-mm flaccid bulla on the left buccal mucosa.

A biopsy specimen taken from the soft palate showed only subepithelial inflammation. Biopsies of skin from the left scapular area and the right knee showed inflammatory subepidermal bullae consistent with pemphigoid. Results of an ophthalmologic examination were normal.

*SEB indicates subepidermal bulla; BMZ, basement membrane zone; and ICS, intercellular substance.

Roentgenograms of the spinal column showed compression fractures of thoracic and lumbar vertebrae (T-6 through T-10, T-12, and L-1). A bone biopsy (ninth right rib) was characteristic of hypercortisonism. Proctosigmoidoscopy and barium examination of the gastrointestinal tract showed no abnormality. Sulfapyridine (500 mg) was given orally four times daily; this, along with topical steroid creams, seemed to control the skin disease and allowed the dosage of prednisone to be tapered from 30 to 15 mg daily. Sulfapyridine blood levels were more than adequate on two occasions (8.2 and 9.6 mg/100 ml). Also prescribed were sodium bicarbonate to alkalinize the urine, anabolic steroids and a back brace for the osteoporosis, and a strict diet for the diabetes. The patient was dismissed after a 29-day hospitalization and was estimated to be 60% improved. The dosage of prednisone was gradually tapered and was discontinued by June 1968. The anabolic steroid was stopped at the same time. His disease was well-controlled with the sulfapyridine, and erosions developed only after trauma.

In September 1968, however, the patient decided to discontinue the use of sulfapyridine; six weeks later, the generalized

Fig 1.—Bullae on ankle.

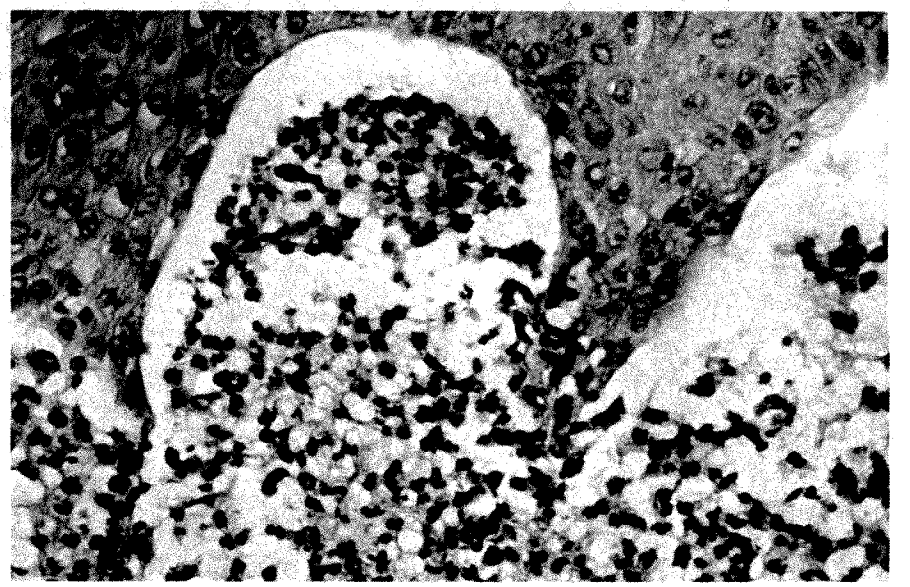

Fig 2.—Papillary neutrophilic microabscesses (hematoxylin-eosin, original magnification ×400).

blistering eruption recurred with the lesions most prominent on the scalp, in the groin, and in the mouth. Considerable dysphagia also developed. He returned to this clinic in November 1968 and was again hospitalized. A barium swallow showed no adhesions, but a 4-cm diverticular pouch was noted anterior and to the right of the aortic arch. On esophagoscopy, numerous ulcerations were apparent in the hypopharynx and esophageal introitus. Much of the esophagus was covered with a whitish membrane, which was friable and bled easily, and two adhesions were noted and lysed. An esophageal biopsy specimen showed nonspecific inflammation, and culture revealed *Candida albicans* and *Streptococcus viridans*, but viral cultures were negative. Serum (indirect) immunofluorescent examinations on two occasions showed antibasement membrane zone antibodies to be present in a titer of 1:320 and 1:160. The patient was again treated with 500 mg of sulfapyridine four times daily given with sodium bicarbonate; a blood level of 5.2 mg/100 ml was achieved. Steroids were used topically on the scalp. The patient again responded well with 80% improvement during his 21-day hospitalization. He was dismissed in late November 1968 and was not seen again at this clinic.

A follow-up letter in 1975 revealed that the patient had died of unknown causes in February 1970 and that his cutaneous disease had remained well-controlled on the sulfapyridine.

CASE 2.—An obese 66-year-old Iowa housewife came to this clinic in August 1967 with an eight-month history of papulovesicular and bullous eruption that had begun on the palms and had become generalized over a few weeks. Nasal and oral ulcerations also were noted. The amount of pruritus was moderate. One month before the onset of the eruption, the patient was found to be diabetic and an oral sulfonylurea was begun; at the same time she had a urinary tract infection and had been treated with an unknown antibiotic. She had been hospitalized elsewhere soon after the onset of the eruption that was thought to be due to a drug. She was treated with steroids used topically only.

On presentation at this clinic, the patient was noted to have numerous excoriated, erythematous papular lesions in a generalized distribution but with accentuation over the extensor extremities. A 5 × 7 cm tense bulla was noted over the left medial malleolus (Fig 1), and a recently ruptured 4-mm vesicle was noted on the left buccal mucosa. Splenomegaly also was noted.

A specimen of skin taken from the right arm for biopsy showed a subepidermal bulla with peripheral papillary neutrophilic microabscesses (Fig 2). Liver function and hematologic measurements were within normal limits, but in view of the patient's severe splenomegaly, laparotomy and splenectomy were performed. Splenic pathological findings showed severe fibrocongestive changes, and liver biopsy revealed fatty change and early portal cirrhosis. A roentgenogram of the chest, barium examination of the entire gastrointestinal tract, excretory urogram, and a mammogram revealed no evidence of malignancy. Results of tests for fat in a 24-hour stool were normal.

The patient was treated with antihistamines and topical fluorinated corticosteroids, and 95% improvement was obtained during her 24-day hospitalization. Her diabetes responded to vigorous dietary control, and the oral hypoglycemic agent was discontinued.

After her dismissal, the patient did well and was able to control her disease topically until early July 1968 when the bullous eruption flared. She returned to this clinic and was noted to have numerous tense 1- to 1.5-cm bullae over the extensor surfaces of the extremities and scattered papular excoriated lesions over the buttocks and back. No mucosal lesions were present. The patient had also gained 32.7 kg (72 lb) over the previous ten months. She was again hospitalized. Biopsy of a specimen from the right volar forearm showed a subepidermal bulla with papillary microabscesses. The serum (indirect) immunofluorescent test showed antibasement membrane zone antibodies to be present in a titer of 1:640. Direct immunofluorescent examination revealed IgG, IgM, and C3 at the basement membrane zone of lesional skin. Uninvolved skin showed nothing on direct immunofluorescent testing. The patient had restarted the oral use of the hypoglycemic agent, and in light of her poor adherence to her diet, this was continued. She was treated topically for her dermatosis, and in addition, 900 mg of sulfapyridine was given orally four times daily with appropriate doses of sodium bicarbonate. A sulfapyridine blood level of 3.2 mg/100 ml was achieved, and the eruption was rapidly controlled. She was dismissed from the hospital after 12 days.

The patient was not seen again at this

clinic. A follow-up letter in 1975 revealed that she had died of unknown causes in April 1972.

CASE 3.—A 45-year-old man first came to this clinic in January 1969 with a 35-month history of a pruritic, generalized papulovesicular eruption that had begun on the scalp and chest. Results of a biopsy done elsewhere seemed consistent with dermatitis herpetiformis, and administration of sulfapyridine for two to three weeks was followed by resolution of the lesions. The patient suffered intolerable nausea while taking this medication, however, and it was discontinued. Trials of sulfoxone (Diasone), dexamethasone (0.75 mg four times daily), and dapsone had failed to control the dermatosis, and he was referred to this clinic.

On examination, the patient was noted to have a generalized, symmetrical excoriated papular eruption with scattered vesicles and rare large bullae and eroded areas. Vesicles and bullae had arisen on both normal and urticarial skin. One erosion was noted on the right buccal mucosa. A biopsy specimen of skin from the left arm showed subepidermal bulla with eosinophilia. Indirect immunofluorescent examination showed antibasement membrane zone antibodies in a titer of 1:2,560, and results of serial titers over the next 15 months were 1:2,560, 1:640, 1:320, and 1:320. Routine tests showed results in the normal range, and sigmoidoscopy and a barium examination of the entire gastrointestinal tract did not reveal evidence of malignancy. Administration of an enteric-coated sulfapyridine was started and was well tolerated, along with appropriate amounts of bicarbonate. Taking 1 gm of sulfapyridine four times daily, a blood level of 7.1 mg/100 ml was achieved. Steroids were used topically, concurrently, and the patient's dermatosis cleared rapidly; he was dismissed after ten days.

The eruption continued to be well-controlled with sulfapyridine, which was reduced to one tablet per day over the next two years. At the time of this report, the patient has not returned to this clinic since 1970; however, a follow-up letter in 1975 revealed that he still required sulfapyridine to control the dermatosis, but that otherwise he was doing well.

CASE 4.—A 46-year-old man came to this clinic in March 1974 with a three-month history of generalized vesiculobullous eruption. The process had begun with oral bullae that had developed two weeks after having a tooth extracted. The nasal mucosa was soon involved, and the bullous lesions gradually spread to the axillae, groin, and legs. The pruritus was described as moderate, but "burning" was considerable. A biopsy done elsewhere showed a "subepidermal bulla most consistent with bullous pemphigoid." The patient was treated with varying intramuscular and oral doses of triamcinolone, which controlled the eruption in amounts of 16 mg or greater daily; but he had repeated flare-ups when the steroids were tapered below this level.

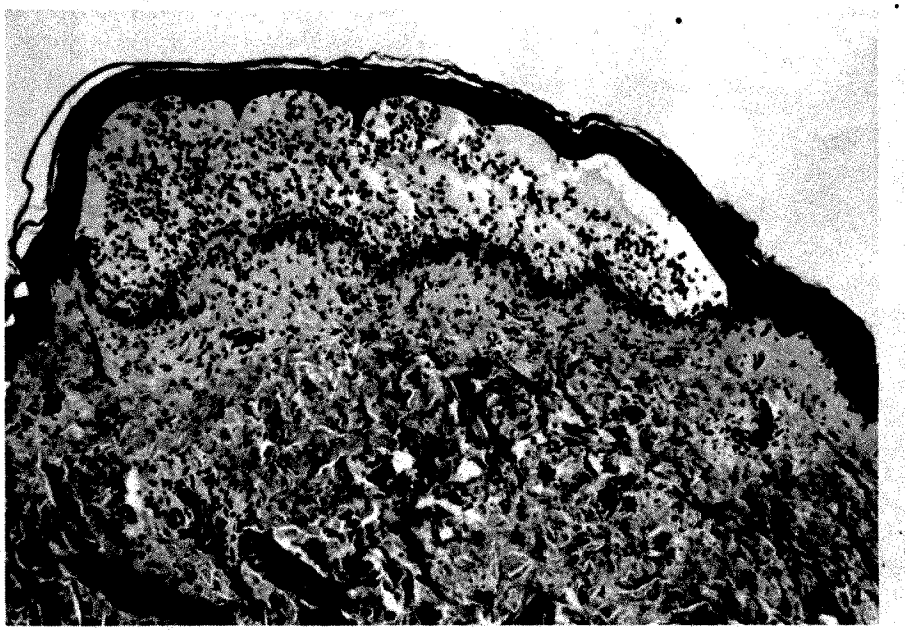

Fig 3.—Low-power view of bulla (hematoxylin-eosin, original magnification ×100).

On admission to this clinic, the patient had numerous 4- to 10-mm tense vesicles and bullae arising on an erythematous base in the axillae, left groin, abdomen, and left supraclavicular area. Moderate obesity and multiple actinic keratoses also were noted. Biopsy specimen from the right axilla was interpreted as showing subepidermal bulla consistent with bullous pemphigoid (Fig 3 and 4). Direct immunofluorescent examination revealed IgG, IgM, C3, properdin, C1q, and factor B in a linear pattern at the basement membrane zone. Indirect immunofluorescent testing demonstrated antibasement membrane zone antibodies in a titer of 1:20. Results of routine laboratory tests were in the normal range. Administration of enteric-coated sulfapyridine, 650 mg three times daily, was begun with rapid regression of the bullae and excellent control of the eruption.

The patient was next seen in June 1974 and was free of blisters. Results of the indirect immunofluorescent test were positive for antibasement membrane zone antibodies in a titer of 1:80, and a sulfapyridine blood level was 3.9 mg/100 ml. He was last seen in October 1974 and continued to be free of lesions while taking the sulfapyridine. Indirect immunofluorescent testing, however, showed anti-intracellular substance antibodies in a titer of 1:320. Unfortunately, we have been unable to obtain follow-up information on this patient.

CASE 5.—A massively obese, 55-year-old woman was first admitted to this clinic in February 1974 with a two-year history of generalized bullous eruption. The lesions had begun on the arms as a maculopapular eruption that had developed one day after having had a tetanus toxoid injection; during the next few weeks, a generalized bullous eruption, characterized by numerous, tense, dime-sized bullae, began to appear. Oral, conjunctival, and nasal lesions also were noted. The lesions were intensely pruritic. The patient had had numerous evaluations of the eruption elsewhere; a previously taken biopsy specimen had shown a subepidermal bulla, and results of immunofluorescent studies were reported to the patient as negative. She had had an unsuccessful trial of an unknown sulfa preparation, but significant improvement followed the systemic use of steroids and dapsone. Unfortunately, the former exacerbated the patient's mild congestive heart failure and unmasked previously unrecognized diabetes mellitus; and the latter had to be discontinued because of anemia. She was then referred to this clinic.

On initial examination, a generalized, symmetrical vesiculobullous eruption without regional accentuation was noted. The blisters were tense and 3 to 10 mm in diameter; most had been excoriated. Mucosal lesions were limited to the oral and nasal mucosa. Biopsy specimens of skin

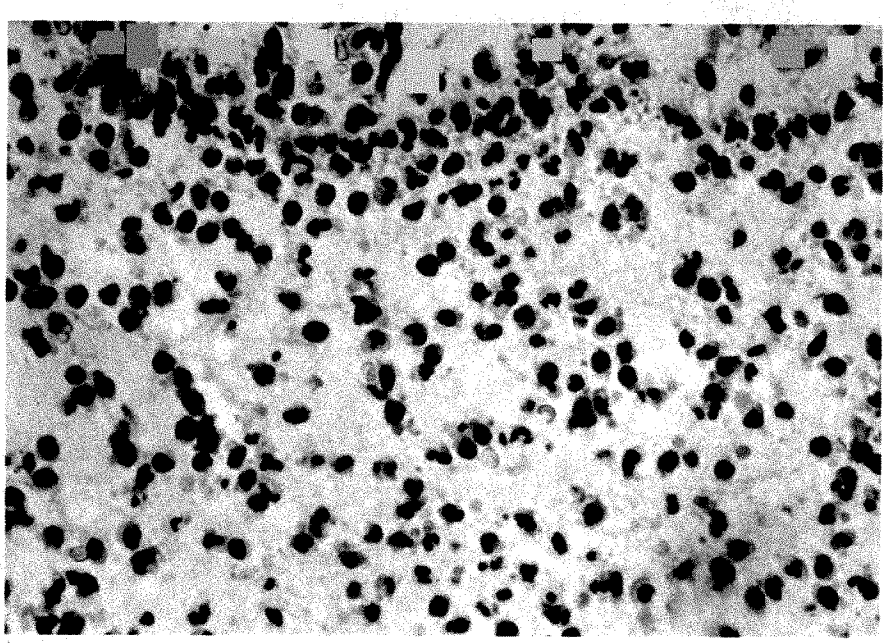

Fig 4.—High-power view of bulla showing predominantly neutrophilic infiltrate (hematoxylin-eosin, original magnification ×500).

from the left arm revealed inflammatory subepidermal bullae most consistent with erythema multiforme. Biopsy specimens of tissues from the back and palate showed nonspecific results. Direct immunofluorescent examination of lesional skin revealed a linear pattern of IgA, C1q, and properdin at the basement membrane zone. A repeat direct immunofluorescent examination one week later revealed a linear pattern of IgG, IgM, IgA, fibrin, C1q, factor B, C3, and properdin at the basement membrane zone. Indirect immunofluorescent testing was negative on one occasion; on another it showed antibasement membrane zone antibodies in a titer of 1:80. Mammography, sigmoidoscopy, and barium examination of the gastrointestinal tract were negative for malignancy. The patient's diabetes was controlled by diet. A gynecologic consultation for postmenopausal hemorrhage revealed only a cystocele and rectocele, and dilatation and curettage was adamantly refused. The patient was treated for her dermatosis with topical fluorinated corticosteroids, antihistamines, and sulfapyridine. A sulfapyridine blood level of 3.5 mg/100 ml was achieved, and she was dismissed considerably improved.

The patient has not been seen at this clinic since, but a follow-up letter from her in November 1975 revealed that she was taking dapsone with good, but not complete, control of her dermatosis.

CASE 6.—A 58-year-old woman came to this clinic in January 1974 with a six-week history of a generalized bullous eruption that had begun on her arms and gradually spread to the legs, back, and abdomen. Pruritus was moderate. Previous treatment had included topical use of steroid creams, antihistamines, and an unknown intramuscular injection.

On her admission to this clinic, physical examination showed an erythematous papular, occasionally excoriated, eruption on the back, abdomen, and extremities with scattered tense blisters ranging in size from 0.3 to 2.5 cm. Most of the blisters were in flexural areas, and there were no mucosal lesions.

Biopsy specimens from the abdomen and leg revealed nonspecific dermal inflammation. Direct immunofluorescent examination revealed a linear deposition of C3, fibrin, and properdin at the basement membrane zone on one occasion, and two weeks later it showed IgG and C3 in a linear pattern in the same zone. Indirect immunofluorescent testing revealed antibasement membrane zone antibodies in a titer of 1:20. Sigmoidoscopy, barium examination of the entire gastrointestinal tract, excretory urogram, and cervical smear showed no evidence of malignancy. Dilatation and curettage, performed because of postmenopausal bleeding, revealed only atrophic endometrium. Mild glucose intolerance was noted with the fasting plasma glucose ranging from 91 to 131 mg/100 ml (upper limit of normal, 100 mg/100 ml).

Treatment included topical use of steroid creams and oral administration of enteric coated sulfapyridine, 650 mg three times daily, with appropriate amounts of sodium bicarbonate. This achieved a sulfapyridine blood level of 7.4 mg/100 ml. The patient responded rapidly to this regimen, with a 90% clearing of lesions and no new bullae during her 19-day hospitalization.

Over the next year, the patient remained free of blisters while taking sulfapyridine. Serial indirect immunofluorescent tests over this period showed the following titers of antibasement membrane zone antibodies: 1:20, 1:20, 1:20, 1:40, negative, negative. The patient, meanwhile, gradually reduced the sulfapyridine and found that 1,300 mg in one weekly dose would control the eruption.

The patient has not been seen at this clinic since February 1975. A follow-up letter, however, revealed that she discontinued use of the sulfapyridine entirely in May 1975 without ill effects. Erythematous guttate macular lesions develop occasionally; she treats these topically with steroid creams. Thus far, this has completely controlled her disease.

COMMENT

Discernible differences were noted between the sulfa-responsive patients and those with typical bullous pemphigoid. The sulfa-responsive patients were younger, with a mean age of 54 years. Histopathologically, neutrophilic infiltration was more common and more dense, while eosinophils were less common than is usual in pemphigoid; but only one patient showed the papillary neutrophilic microabscesses typical of dermatitis herpetiformis.[7-11] Three of the six patients had overt adult-onset diabetes mellitus, and a fourth had an elevated fasting blood sugar that was not in the diabetic range. Interestingly, at last report one patient (case 4) had a negative titer of basement membrane zone antibodies, but a titer of 1/320 to the intercellular substance antibody had developed. He may be evolving into the sulfa-responsive pemphigus group mentioned,[7-10,12,13] but evolution is unclear at this time.

Despite these minor differences, however, we believe that all six cases represent bullous pemphigoid. Clinically, only one patient (case 6) did not have oral lesions. As previously mentioned, papillary microabscesses were apparent on histopathologic examination in only one patient (case 2). All patients on whom direct immunofluorescent examinations were performed showed linear deposition of IgG and other immunoreactants characteristic of pemphigoid.[15,16] Although

the presence of a linear deposition of IgA (case 5) is mildly suggestive of dermatitis herpetiformis, the presence of IgG, IgM, C3, factor B, properdin, and C1q in a linear pattern is most consistent with the pemphigoid spectrum of diseases.[16] All six patients had circulating antibasement membrane zone antibodies on at least one occasion by indirect immunofluorescent testing—again, characteristic of bullous pemphigoid.[16,17]

These patients emphasize the necessity for immunopathologic confirmation in the diagnosis of bullous dermatoses. We believe that some confusion has arisen from the use of sulfapyridine and the sulfones as a supposedly specific therapeutic test for dermatitis herpetiformis. Our contention is that a response to sulfapyridine or sulfones is a sensitive indicator of dermatitis herpetiformis, but we do not believe that it is a specific indicator of the disease.

The mechanism of action of sulfapyridine and the sulfones in these patients is unknown. These agents also have been used with some success in many other dermatoses, including pyoderma gangrenosum,[18,19] subcorneal pustular dermatosis of Sneddon-Wilkinson,[20,21] acrodermatitis continua (acrodermatitis of Hallopeau),[22-24] erythema elevatum diutinum,[25-27] acne conglobata,[28] and necrotizing angiitis.[29,30] All these dermatoses are characterized histologically by polymorphonuclear leukocyte infiltration of varying but significant degree. The well-known response of ulcerative colitis to salicylazosulfapyridine is probably similarly grouped.[31] It seems reasonable to assume that sulfapyridine and the sulfones might act by inhibiting neutrophilic function in some way.

Barranco[32] presented evidence that dapsone may inhibit lysosomal enzymes in rabbits with induced hypervitaminosis A. Normally, hypervitaminosis A results in lysosomal instability with subsequent enzyme release and breakdown of chondroitin sulfate in the cartilage of affected animals. In the rabbit, the visible result is floppy ears, and dapsone, like methylprednisolone, will prevent this effect. Mier and van den Hurk[33] have recently presented evidence that the concentration of dapsone that directly inhibits such enzymes is 20-fold the serum concentration. Thus, unless dapsone is concentrated by lysosomes, direct enzyme inhibition may not be its mode of action. However, any mechanism that inhibits the function of neutrophils, lysosomes, or lysosomal enzymes would account for the histologic similarities of the diseases in which sulfapyridine and the sulfones are effective. One also wonders if the rare, idiosyncratic agranulocytosis occurring with these drugs might somehow be related to this effect. If a sulfapyridine or sulfone effect on neutrophils is indeed responsible for their therapeutic efficacy, finding a predominance of neutrophils over eosinophils on biopsy of a bullous pemphigoid lesion may be therapeutically significant.

Immunofluorescent studies were performed in the laboratory of Robert E. Jordon, MD.

Chloracne From Manufacture of a New Herbicide

James S. Taylor, MD; Richard C. Wuthrich, MD; Kenneth M. Lloyd, MD; Alan Poland, MD

• Forty-one chemical company workers had chloracne as a result of exposure to 3,4,3′,4′-tetrachloroazoxybenzene (TCAB), an extraneous intermediate produced during the manufacture of a new herbicide. There was no laboratory evidence of significant hepatotoxicity or porphyria during the short time the herbicide was produced. An acnegenic when applied to the rabbit ear, TCAB is also a potent inducer of the microsomal enzyme aryl hydrocarbon hydroxylase. Prevention of chloracne is a difficult industrial engineering task and treatment of the disease is even more perplexing.

(*Arch Dermatol* 113:616-619, 1977)

Chloracne is an extremely refractory form of occupational acne produced by exposure to various chlorinated aromatic compounds, and may be accompanied by serious systemic toxicity.[1-4] These chemicals are also environmentally important, having produced epidemics of X disease in cattle and chick edema in chickens. Many are teratogenic.[5]

This report describes the first reported cases of chloracne from 3,4,3′,4′-tetrachloroazoxybenzene (TCAB), an extraneous intermediate formed during the manufacture of the new herbicide, 2-(3,4-dichlorophenyl)-4-methyl-1,2,4-oxadiazolidine-3,5-dione.[6,7] Workers in a small chemical company first noted cases of the "bumps" one to two months after herbicide production began. We first visited the company several months later when more than 90% of the workers had chloracne.

METHODS

Clinical

Forty-one workers participated in a study that included relevant dermatologic history and examination. A quantitative screening test for total porphyrins (method of Schlenker, and Kitchell)[8] and an SGOT were obtained from 37 and 32 workers, respectively. Skin biopsy specimens of chloracne lesions were obtained from two workers.

Experimental

Acetone solutions of 0.1%, 0.001%, and 0.0001% technical grade TCAB were applied to the ears of 2.3- to 3.2-kg albino rabbits, according to the method of Adams et al.[9] Solutions were applied daily (five days of seven) for four weeks and acnegenic responses were recorded weekly. Acetone and 50% Halowax 1014 in mineral oil served as negative and positive controls, respectively.

Following injections of TCAB and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) the activity of aryl hydrocarbon hydroxylase (AHH) in chick embryo liver was assayed, as previously described by Poland and Glover.[10] The TCDD is a potent chloracnegen and also an inducer of δ-aminolevulinic acid synthetase.

RESULTS

Clinical

The clinical results are summarized in Table 1 and Fig 1 through 8.

Experimental

Rabbit ear bioassay results are summarized in Table 2. In addition to the comedone formation, the 0.1% TCAB acetone solution was irritating to the rabbit ear, producing erythema, edema, and necrosis of the epithelium. The higher dilutions were nonirritating. The 0.1% and 0.01% solutions of the final product (herbicide) were only slightly irritating (D. D. Knutson, MD, written communication June 1974). Dennis D. Knutson, MD, of the University of Oregon Medical School, also tested TCAB by rabbit ear bioassay and found a 0.05% TCAB alcohol solution to be acnegenic.

The results of AHH induction by TCAB and TCDD in chick embryo liver are summarized in Table 3. A standard dose of TCDD, which elicits about 70% of the maximal response,

Accepted for publication July 23, 1976.

*2,3,7,8-tetrachlorodibenzo-*p*-dioxin is indicated by TCDD; 3,4,3′,4′-tetrachloroazoxybenzene, TCAB.

was administered for comparison. The TCAB is about one half as potent as TCDD. Both compounds elicited the same maximal induction of AHH, and maximally induced doses of both drugs administered simultaneously produced no greater response than that produced by either drug alone (data not shown).

COMMENT

The herbicide was manufactured in a two-story building subdivided into partially enclosed bays, and TCAB was formed as an extraneous intermediate during an early stage of the production. Exposure to TCAB occurred around centrifuges and discharge stills by direct skin contact during loading, unloading, and maintenance of equipment; sampling for laboratory analysis; and accidental breaks in pipes. Aerosolization of the TCAB during centrifugation with resultant inhalation or ingestion was also possible. Only a fraction of a percent of the contaminant TCAB is present in the final product (herbicide), and no chloracne has occurred in the plant where the herbicide is formulated. Equipment available for the workers included rubber aprons, face shields, sleeves, gloves, work uniforms, hard hats, safety glasses, and boots. The acne lesions ranged from large fluctuant cysts to typical straw-colored cysts, comedones, and pustules. In most workers the chloracne appeared during their first two months of employment (ranging from one week to eight months). It was not possible to fully evaluate the systemic complaints, except to determine that the workers with hirsutism and dark urine had no evidence of porphyria.

Family members of four workers, who had never been inside the plant, developed chloracne. Direct contact most probably occurred because contaminated work clothes or tools were brought home.

The company instituted significant personal hygiene and industrial engineering changes, but production ceased two months later without adequate evaluation of these improvements.

As has been the experience of others[1-4,11] we found chloracne to be extremely refractory to treatment with the usual measures employed for acne vulgaris. Acne surgery was probably most beneficial, and a combination of tetracycline and short courses of orally administered prednisone helped in those workers with severe inflammatory cases. A trial regimen of methotrexate, 25 mg every ten days for several months, did not help the most severely affected worker. Most recently, success in treating chloracne has been reported by Plewig,[12,13] with use of varying concentrations (0.05% to 0.3%) of vitamin A acid (retinoic acid) in different bases. We found vitamin A acid solution or cream to be beneficial in the mild cases with comedones and papules. Approximately 40% of the workers, including some of those with more severe cases, are now free of active acne lesions, including comedones. In one outbreak, chloracne was reported to persist as long as 15 years after all exposure to the chemical had ceased.[14] The most essential part of any treatment program is recognition of the problem and strict avoidance of any further exposure to the chloracnegen.

The acnegenicity of the TCAB was confirmed by use of rabbit ear bioas-

say, but other herbicide intermediates should also be investigated. The herbicide itself is not acnegenic and no chlorinated dibenzo-*p*-dioxins are produced during its manufacture. The chlorinated dibenzo-*p*-dioxins have a number of similarities to TCAB. The prototype compound, TCDD, is formed as a trace contaminant during the manufacture of the herbicide, 2,4,5-trichlorophenoxyacetic acid. This compound has produced chloracne in workers and has been experimentally produced in the rabbit ear test.[10] In addition, TCDD is hepatoxic, teratogenic, and porphyrinogenic.[5,10] Both TCDD and TCAB, at very low doses (10^{-10} moles/egg), induce hepatic AHH activity, a microsomal monooxygenase responsible for aromatic hydroxylation of numerous compounds.

Although there was no laboratory evidence of significant hepatotoxicity among the workers, a more complete and long-term physical and laboratory evaluation is indicated.

Evidence for chlorobenzene compounds causing chloracne is sketchy.[2] A few cases were reported during dichlorodiphenyltrichloroethane (DDT) manufacture,[15] and most recently chloracne has been reported in workers producing the herbicide 2,6-dichlorobenzonitrile.[16] Both reports are clinical and no studies on the toxicity of intermediate compounds are mentioned. Rimington and Ziegler[17] produced keratotic plugging of follicles with sebaceous gland atrophy after feeding rats 1,2,3,4-tetrachlorobenzene.

We know of two other outbreaks of chloracne from TCAB during herbicide manufacture, one in Great Britain (Donald Williamson, MB, written communication, May 1974) and the other in the United States. In the former cases electron microscopic studies of the pilosebaceous ducts were similar to those previously reported for acne vulgaris.[18]

The extreme toxicity of the herbicide intermediate TCDD has great environmental importance.[5,10] Because azobenzene compounds similar to TCAB may be produced in minute quantities by the action of soil bacteria on certain aniline pesticides,[19] TCAB may also have potential environmental impact.

In conclusion, chloracne is a cutaneous disease that represents one form of biologic response to certain chlorinated aromatic compounds. Chloracne serves as a marker of the medical and environmental impact of contamination of technical grade chemicals with potentially highly toxic intermediates.

Since the acceptance of this paper for publication, another article[20] has been published and shows the ability of TCAB and its congeners to induce AHH correlates with their capacity to induce acne.

This report was supported in part by the Cleveland Clinic Foundation research project CRP-100 and by the National Institute of Environmental Health Sciences grant 1-RO1-ES-00965-03.

Frequency of Application on Percutaneous Absorption of Hydrocortisone

Ronald C. Wester, PhD; Patrick K. Noonan; Howard I. Maibach, MD

• This study determines the percutaneous absorption of hydrocortisone when applied as a single dose or on a repetitive basis. Application was to the shaved ventral forearm of the rhesus monkey, an animal model in which some relevance to man has been shown. Absorption was quantified by measuring ^{14}C in aliquots of urine over five days. There was no substantial difference in total absorption when 13.3 μg/sq cm was applied as a single dose or when the 13.3 μg/sq cm was applied three times, totaling 40 μg/sq cm. However, when 40 μg/sq cm was applied as a single dose, absorption was substantially increased over 13.3 μg/sq cm applied either once or three times. Additionally, when the skin was washed between applications to remove previously applied material in the three application experiment, there was a statistically significant increase over *not* washing the skin. The clinical importance of these results to man will await appropriate clinical studies.

(*Arch Dermatol* 113:620-622, 1977)

Most physicians, by tradition, recommend to patients that therapeutic agents be applied to skin on a repetitive basis. For instance, topical corticoids package inserts suggest two to four applications daily; in fact, in the hospital situation it is not unusual to apply it even more frequently. This study documents the effect of single repetitive application of hydrocortisone on the total quantity of compound absorbed. This study is performed in an animal model that may reflect the situation in man.

MATERIALS AND METHODS

Absorption was quantified on the basis of the percent radioactivity excreted in urine for five days following application of a known amount of the labeled compound to the skin. This method used for measuring percutaneous penetration is the procedure of Feldmann and Maibach[1,2] that has been adapted to the rhesus monkey.[3] Methodology is detailed within these papers.

Female rhesus monkeys (4 to 8 kg), trained for metabolic studies, were randomly selected from the colony. The only criteria for selection was that the animal was clear of any previously administered ^{14}C-compound. Hydrocortisone labeled with radioactive carbon (^{14}C) was applied to lightly clipper-shaved skin of the ventral forearm. Previous experience with testosterone absorption showed that shaving does not alter penetration in this animal.[3] Each application dose contained 5 μCi of radioactivity. The area was not occluded[3] and the application area was always a constant 6 sq cm.

For topical application the monkeys were placed in a metabolism chair for the first 24 hours of the study. The hands of the monkey were secured to the sides of the chair to avoid its wiping off the applied compound. The animals were not anesthetized during the study. Hydrocortisone was applied to the skin in acetone, and the solvent quickly evaporated by gentle blowing. For the next 24 hours urine was collected in a container below the metabolism chair. Then the site of application was washed with soap and water and the monkey returned to a metabolism cage to continue the urine collection. In the metabolism chair the site of application is totally separated with a barrier from the area of urine collection. This insures against any possibility of chemical falling off the skin and contaminating the urine.

Daily urinary excretion values were corrected for excretion of radioactivity by other routes and retention of radioactivity in the body by administration of an intravenous dose of hydrocortisone ^{14}C.[3]

The percent dose excreted was based on the total amount of compound applied to the skin during the first 24-hour period. This would be the percent of the single dose applied, and when three applications, the percent of the total accumulated dose. All data were then calculated to percent absorption based on a square centimeter area.

RESULTS

The data for the percutaneous absorption of hydrocortisone are given in Tables 1 and 2 and in the Figure. Table 1 shows the percutaneous absorption values expressed as

Table 1.—Percutaneous Absorption of Hydrocortisone Following Single and Multiple Dose Applications to Rhesus Monkey Skin

Topical Dose, μg/ sq cm	Application*	No. of Animals	Percent Dose Excreted, hrs†					Total Absorption ±SD†	
			0-24	24-48	48-72	72-96	96-120	Percent	Area, μg/sq cm
13.3	1X	5	0.25	0.45	0.27	0.20	0.20	1.37 ± 0.97	0.18 ± 0.13
13.3	3X (no wash)	4	0.06	0.18	0.11	0.11	0.10	0.55 ± 0.06	0.22 ± 0.03
13.3	3X (wash)	3	0.17	0.21	0.16	0.08	0.10	0.72 ± 0.06	0.29 ± 0.02
40.0‡	1X	3	0.95	0.68	0.27	0.13	0.07	2.1 ± 0.6	0.84 ± 0.25

*1X is single dose applied for 24 hours, then area washed with soap and water. 3X is three applications (9 AM, 2:30 PM, 9 PM), then area washed with soap and water 24 hours after first application. "No wash" is dose applied over previous dose. "Wash" is area washed with soap and water immediately prior to applying next multiple dose.

†Values are corrected for incomplete excretion.

‡Data previously reported.[6]

percent absorbed and as micrograms of absorption per square centimeter area of application. Table 2 summarizes the statistical comparisons between group means for the absorption values as micrograms per square centimeter.

One application of 13.3 μg of hydrocortisone/square centimeter area was the baseline concentration applied to skin. When the same dose was applied three times (without any washing) there was a slight but not statistically significant increase in absorption.

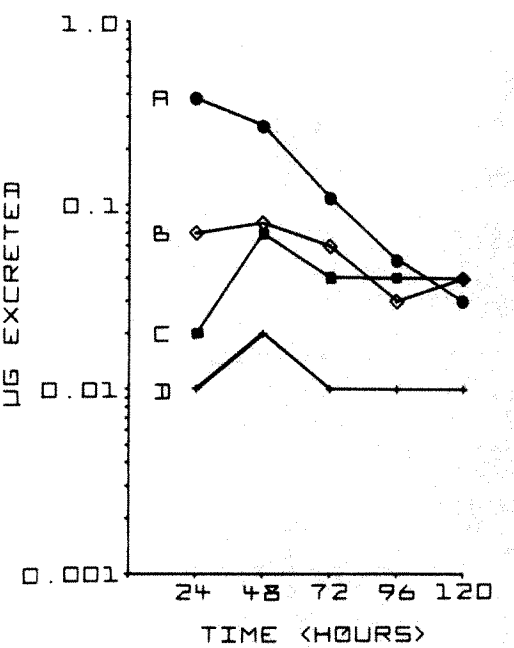
The more important point is that when this is compared to one single application of 40 μg/sq cm, there was a large and statistically significant ($P < .05$) increase over 13.3 μg/sq cm applied either once or three times.

When the skin was washed between applications in the three application experiment, there was a statistically significant increase ($P < .05$) over not washing the skin.

COMMENT

It is not possible to compare this data to percutaneous absorption data from previous experiments as there is no literature available on the pharmacokinetics of single and multiple application of topical compounds.

The first question that might be asked is what is the relevance of the monkey to human percutaneous absorption. Limited experiments document that at least in some situations the parallel in penetration is striking. These experiments have been limited to application of the radioactive labeled chemical on the intact skin of



Effect of frequency of application on percutaneous absorption of hydrocortisone from ventral forearm of rhesus monkey. Ordinate is micrograms excreted and abscissa is time (hours). Each point represents mean microgram excreted in urine per square centimeter area of topical application of hydrocortisone. A is 40 μg/sq cm of hydrocortisone applied once; B and C are 13.3 μg/sq cm applied three times (total to 40 μg/sq cm) with area washed between applications for B; D is 13.3 μg/sq cm applied once.

Table 2.—Summary of Statistical Comparison Between Two Group Means: Absorptions as Micrograms per Square Centimeter Area

First Group, μg/sq cm	Secong Group, μg/sq cm	t Value*
13.3—1X	40—1X	5.00†
13.3—1X	13.3—3X (no wash)	0.53
13.3—1X	13.3—3X (wash)	1.35
40—1X	13.3—3X (no wash)	5.10†
40—1X	13.3—3X (wash)	3.80†
13.3—3X (no wash)	13.3—3X (wash)	3.87†

*Student two-tailed *t* test.
†Significant difference ($P < .05$).

the forearm of the rhesus monkey[3,4] and back skin of the squirrel monkey[5] in comparison to man. The compounds previously studied include hydrocortisone, testosterone, and benzoic acid in the rhesus and the pesticides DDT, gamma benzene hexachloride (lindane), parathion, and malathion in the squirrel monkey. Only for melathion was there a notable difference between a monkey (squirrel) and man. From these observations it appears that the forearm of the rhesus is a reasonable model for the forearm of man.

Additional correlative data are those of dose (concentration) response curve studies done on the percutaneous absorption of the rhesus monkey in vivo and man in vivo.[6] In these studies dose response curves for hydrocortisone, testosterone, and benzoic acid going from a range of 4 μg/sq cm to 400 μg/sq cm show similar results. This, again, suggests a close correlation between the two models for these three chemicals.

The results seen here are surprising, indeed. Common sense suggests that repeated applications would produce substantially more penetration. This is not the case for hydrocortisone in this model and in this vehicle system. We cannot predict that the same will occur for human skin, although the possibility does seem reasonable. There are also no data on diseased skin that would allow us to extrapolate to this at present. Also, we do not know if this observation will hold for other chemicals.

In the data for hydrocortisone it is clear that 40 μg/sq cm produced substantially more penetration than did the 13.3 μg/sq cm applied three times in the day. It is known from previous dose response studies[6] with one application that generally the more one applies to the skin the more penetration that will occur. This response is not necessarily linear for all compounds. The practical ramification is that it is possible that one application of a high concentration may in fact be more effective than several applications of a lower concentration. We emphasize, though, that this pharmacokinetic data should not be interpreted out of context but that it should point the way to appropriate clinical studies to verify this point.

It is curious that removing the hydrocortisone by washing did not decrease total penetration. Statistically, it produced an increase in penetration. We believe that this observation is of more than passing interest. In prior studies with pesticides (unpublished observations) we have repeatedly observed this phenomenon. This suggests that when we wash off compounds to decrease the chance of toxicity, we may be doing the exact opposite—,increasing the risk of toxicity. Perhaps it is that the soap and water wash hydrates the skin and this would account for the increased absorption when the skin is washed between applications. We do not wish to generalize on this but believe that these observations deserve serious consideration.

J. Pautsch and B. Nicolova, DVM, gave assistance in this study.

Perfume Dermatitis

A Study of 20 Patients

Walter G. Larsen, MD

• Patch tests to several screening sets of fragrance materials were performed on 20 perfume-sensitive patients. The most common allergens were found to be a jasmin synthetic (18 of 20 patients), cinnamic alcohol (15 of 20 patients), and hydroxycitronellal (9 of 20 patients). More than half of the patients were also contact sensitive to other ingredients of cosmetics and over-the-counter and prescription preparations.

***(Arch Dermatol* 113:623-626, 1977)**

Perfumes are complex mixtures consisting of a few to several hundred individual fragrance components. Because of their complexity, there is great difficulty in identifying specific fragrance components responsible for allergic reactions.

Perfume appears to be one of the major allergens found in cosmetics.[1] This study was attempted to identify the specific fragrance chemicals responsible for allergic reactions to perfumes. Cosmetic sensitivity was the complaint from 15 of 20 patients; reactions to over-the-counter or prescription creams accounted for the remaining five.

REPORT OF CASES

Case 1.—An 82-year-old man had perianal dermatitis of 18 years' duration. He had used many different types of over-the-counter preparations containing local anesthetics, antihistamines, and antibiotics. Most recently, he had been using a cream that was a mixture of triamcinolone acetonide, neomycin sulfate, gramicidin, and nystatin (Mycolog). He was intolerant of most lubricating creams and antiperspirants.

He showed positive patch-test reactions to this cream itself and to the following constituents of the cream (see Tables 6 and 7): (1) neomycin; (2) ethylenediamine; and (3) perfume (E-1991). He showed positive patch-test reactions to the following dilu-

tions of the perfume: 5% concentration in petrolatum, 0.5% in petrolatum, 0.05% in petrolatum; there was a negative response at 0.005% in petrolatum.

The 28 components of the cream's perfume were tested individually at a concentration of 5% in petrolatum, and positive reactions to cinnamic alcohol, amyl cinnamic alcohol, and benzyl alcohol were noted.

This patient reacted in the following manner to various concentrations of cinnamic alcohol: positive at 5% concentration in petrolatum, 0.5% in petrolatum, 0.1% in petrolatum, and 0.05% in petrolatum. There was a negative reaction at 0.005% in petrolatum.

CASE 2.—A 48-year-old woman had contact dermatitis of the face and neck. She stated that for years she has reacted adversely to almost all perfumes, cosmetics, and creams.

Patch-testing elicited many positive reactions (Table 8). The dermatitis was finally cleared when she began using nonfragranced materials that were also free of lanolin, quaternium-15 (Dowicil-200), and dichlorophen. It may be noted that quaternium-15, which is a formaldehyde releaser, is finding increasing use as a preservative in topical preparations, and that dichlorophen is used as a preservative in foot powder and in lubricants such as Nivea cream.

COMMENT

Fifteen of the 20 patients came to the office with dermatitis due to a cosmetic. The remaining five patients had dermatitis from a topical medicament (four due to a prepared cream [Mycolog] and one due to a liquid preparation containing phenol and camphor [Campho-Phenique] and a prepared cream containing benzocaine, chlorothymol, and resorcinol [Lanacane]). Five patients were allergic to the prepared cream (Mycolog) (one past relevant) and had positive reactions to ethylenediamine and also to the perfume. Allergy to the perfume in Mycolog cream has previously been reported.[2,3]

Five patients had axillary dermatitis due to the perfume in their deodorant or antiperspirant. From their clinical history, many of the other patients were intolerant of various deodorants and antiperspirants.

I postulate that many of these patients were sensitized to the fragrance materials and other allergens by using topical preparations on eczematous skin. Irritated or eczematous skin is known to be more readily sensitized than normal skin. Some of the patients allergic to cosmetics were possibly sensitized by the use of underarm deodorants or antiperspirants, or both. These preparations are used frequently on a daily basis in a warm, moist occluded area subject to friction. Irritation from axillary shaving plus the presence of an irritant (aluminum salts) might also facilitate sensitization.

A surprising finding in the study was the frequency of positive reactions to other ingredients commonly found in topical medicaments and cosmetics. Allergens, which produced positive reactions, included lanolin, ethylenediamine, neomycin, caine mixture, dichlorophen, methylparaben, quaternium-15, imidazolidinyl urea (Germall 115), sorbic acid, and formaldehyde solution. Some fragrance materials such as benzyl alcohol and benzyl benzoate are used as preservatives as well as in perfumes.

Cinnamic alcohol and hydroxycitronellal were the chemical components most frequently responsible for perfume allergy in the 20 patients. However, in most patients, more than one fragrance substance produced a positive reaction. Nine of 20 patients showed positive reactions to Peruvian balsam. It seems possible that a synthetic jasmin used by the NACDG may prove to be a superior perfume-screening mixture, since 18 of 20 patients showed positive reactions to this formulation.

Cinnamic alcohol is a synthetic aromatic alcohol that is widely used in perfume compositions. Use in frag-

rances in the United States amounts to approximately 6,818 kg per year.[4] Cinnamic alcohol and its esters have been reported to occur in about a dozen natural products, mainly in various resins and balsams.

Predictive testing utilizing the Kligman maximization test on 25 volunteers at a concentration of 4% in petrolatum produced no sensitization reactions to cinnamic alcohol.[4] Jordan repeated this experiment in 1975 with similar results.[5] He then repeated the Kligman maximization test using a different vehicle (ie, cinnamic alcohol, 4%, in ethyl alcohol), and 1 of 27 males was sensitized. Cinnamic alcohol, 4%, in ethyl alcohol was also simultaneously tested by a modified Draize technique, and 4 of 150 subjects were sensitized (4 of 33 females, and 0 of 122 males).[5]

Hydroxycitronellal is one of the most frequently used floralizing perfume materials. Use in fragrances in the United States amounts to more than 22,727 kg per year.[6] Hydroxycitronellal has not been found to occur in nature. However, it is an indispensable ingredient in most perfume compositions.

Hydroxycitronellal tested with the Kligman maximization test on 25 volunteers produced no sensitization reactions.[6] Jordan sensitized 1 of 150 subjects using hydroxycitronellal, 4%, in petrolatum, with the Draize predictive test.[5]

Gutman and Somov patch-tested patients with eczema who worked in a perfume factory with a battery of fragrance materials.[7] They found that cinnamic alcohol was the most common allergen (13 positive reactions in 22 fragrance-sensitive patients). In a more recent study, Novak found that three of ten fragrance-sensitive patients were allergic to cinnamic alcohol.[8]

Some fragrance chemicals are used in dentistry (eugenol), in counterirritants (eugenol, menthol, and camphor), and as preservatives in topical preparations (benzyl alcohol and benzyl benzoate). Chemicals of the cinnamate family are used in toothpastes and sunscreens. Fragrances are frequently used in medicated topical preparations including some topical prescription medications. Therefore, in the evaluation of a patient with contact dermatitis due to a cosmetic or topical medicament, it is important to test with the fragrance component of the preparation.

Fragrance materials that are reported to be sensitizers should be deleted from preparations designed for use on irritated or dermatitic skin.

Abnormal Vascular Reactions in Atopic Dermatitis

Masami Uehara, MD, Shigeo Ofuji, MD

• Vascular reactions to mechanical stroking, topical application of nicotinic acid ester, and methacholine chloride were examined in both the normal and abnormal skin of 100 patients with atopic dermatitis and 20 patients with allergic contact dermatitis. White dermographism, nicotinic acid blanching, and delayed blanch with methacholine consistently occurred in areas of skin with eczematous change of patients with atopic dermatitis and those with allergic contact dermatitis. Normal skin of atopic patients did not show the abnormal vascular reactions. It is suggested that white dermographism, nicotinic acid blanching, and delayed blanch with methacholine seen in atopic dermatitis are secondary phenomena that give no definite information concerning the diagnosis of this disease.

(*Arch Dermatol* 113:627-629, 1977)

Patients with atopic dermatitis commonly show abnormal vascular reactions to mechanical and pharmacologic stimuli. Stroking on the skin is not followed by the normal "triple response," instead there is white dermographism. Lobitz and Dobson[1,2] state that the phenomenon of white dermographism has clinical, diagnostic, and prognostic significance for atopic dermatitis because it is the first to appear as the skin begins to become involved in atopy and it is the last to disappear when the skin is returning to normal. Epicutaneous absorption of nicotinic acid esters normally produces erythema, but yields an "anemic reaction" in patients with atopic dermatitis. The nicotinic acid blanching has also been used as a diagnostic test for atopic dermatitis.[3,4] Intracutaneous injection of methacholine chloride is normally followed by reddening, while patients with atopic dermatitis exhibit blanching around the wheal. The delayed blanch, according to Lobitz and Dobson,[1,2] has great diagnostic significance for atopic dermatitis in the same way as white dermographism. Various investigators[5,6] believe that a thorough knowledge of the abnormal vascular reactions might lead to a better understanding of the pathogenesis of atopic dermatitis.

From a review of the literature,[1-12] however, it was difficult to determine whether patients with atopic dermatitis produce the abnormal vascular responses in both the involved and uninvolved skin or exhibit the abnormal reactions only in their affected skin.

In the present study we examined vascular responses to mechanical stroking, topical application of nicotinic acid ester, and methacholine simultaneously in the diseased and normal skin of patients with atopic dermatitis. The results also are compared with the vascular reactivity of the affected skin of patients with allergic contact dermatitis to the same mechanical and pharmacologic stimuli.

SUBJECTS AND METHODS

A total of 100 patients with atopic dermatitis, 50 children and 50 adults, were selected for this study. The diagnosis was made on the basis of morphology and distribution of skin lesions, clinical course, and a positive family history of respiratory atopy or eczema.

Clinical controls were 20 adult patients with allergic contact dermatitis (12 were cases of contact dermatitis due to cosmetics; 3, cement dermatitis; 2, rubber dermatitis; 2, watchband dermatitis; and 1, photoallergic contact dermatitis due to bithionol). All had suffered from the dermatitis for more than a year. They had lichenified lesions on the face or the forearms. Personal or family history of asthma or eczema was present in (3) of the 20 controls.

Test Sites

The following test sites were used for patients with atopic dermatitis: (1) lichenified patch on the face, the trunk, or the antecubital fossa; (2) dry and rough skin on the trunk or the forearm, which had sallow complexion and exhibited keratosis pilaris-like papules (evidence of scratching was often present); and (3) normal-appearing, bright, and smooth skin on the trunk or the forearm. (Severe cases with acute exacerbation were omitted from this study because the total body of such patients was frequently covered by skin eruptions and dry and rough skin.)

For those patients with allergic contact dermatitis, the following test sites were used: (1) lichenified patch on the face or the

forearm and (2) normal skin on the trunk or the forearm.

Tests with stroking were performed by the test site being firmly stroked with a blunt instrument. Readings of dermographism were classified into red, intermediate, or white.

Tests with tetrahydrofurfuryl ester of nicotinic acid (Trafuril) were performed by a drop of 0.5% thurfyl nicotinate solution placed on the test site and covered with a piece (1 × 1 sq cm) of cellophane. After 15 minutes of the application, readings were made as follows: (1) red indicated severe redness with or without central edema; (2) intermediate, very weak erythema or no reaction; and (3) blanching, substantial pallor with or without peripheral erythema.

Tests with methacholine chloride (Mecholyl) were performed as follows: instead of the intradermal injection, topical application of a drop of 1:1,000 methacholine solution was placed on the test site and the reactions were read as described in the thurfyl nicotinate test.

Histological Examination

Eight biopsy specimens were obtained from the sallow and dry skin on the upper back of adult patients with atopic dermatitis.

RESULTS

Reactions to Stroking

Patients with atopic dermatitis usually produced white dermographism if their lichenified skin was stroked (Table 1). In the sallow and dry skin of these patients, intermediate or white reactions were commonly obtained. When the normal skin without these skin changes was stroked, a typical red line was produced almost constantly. Patients with allergic contact dermatitis showed intermediate or white dermographism if their lichenified skin was stroked (Table 2). When their normal skin was tested, a typical red line occurred constantly.

Reactions to Thurfyl Nicotinate

Patients with atopic dermatitis consistently produced abnormal vascular reactions to thurfyl nicotinate if the test was performed on their lichenified skin (Table 3). In their sallow and dry skin, the reaction also was abnormal in most patients. In their normal-appearing, bright, and smooth skin, however, typical erythematous reactions occurred in almost all of the cases. Patients with allergic contact dermatitis produced abnormal reactions to thurfyl nicotinate if the test was done on their lichenified skin (Table 2), but they showed typical erythematous reactions in their normal skin.

Reactions to Methacholine

Patients with atopic dermatitis almost constantly produced abnormal vascular reactions to methacholine when the test was done on the lichenified skin or the sallow and dry skin (Table 4). But most patients exhibited normal red reactions if the test was performed on their normal, bright, and smooth skin. Patients with allergic contact dermatitis also produced abnormal reactions to the drug if the test was performed on their lichenified skin (Table 2). All of these patients, however, showed typical red reactions when the tests were performed on the normal skin.

Histology of the Sallow and Dry Skin of Atopic Dermatitis

Focal areas of parakeratosis, mild acanthosis, and slight intercellular edema were present in all of the specimens examined (Fig 1). Spongiotic vesicles and migration of mononuclear cells were often seen in the surface epidermis as well as in the follicular wall (Fig 2). The dermis contained perivascular infiltrates of predominantly mononuclear cells.

COMMENT

The present study demonstrated that lichenified skin of patients with atopic dermatitis consistently produced white dermographism, nicotinic

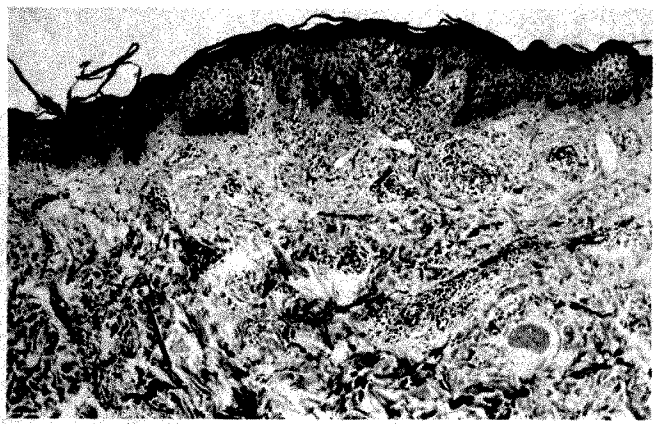

Fig 1.—Sallow and dry skin of atopic dermatitis. Epidermis shows mild acanthosis and intercellular edema. Dermis contains perivascular infiltrate of mononuclear cells (hematoxylin-eosin, original magnification ×40).

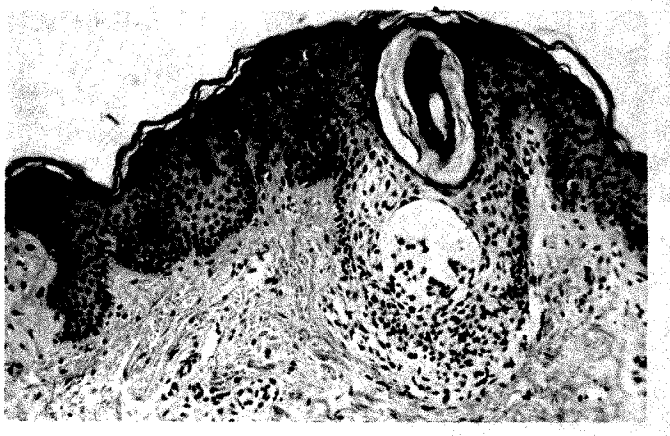

Fig 2.—Follicular change in sallow and dry skin of atopic dermatitis. Note spongiosis, vesicle formation, and mononuclear cell infiltrate (hematoxylin-eosin, original magnification ×100).

acid blanching, and delayed blanch with methacholine, while normal-appearing, bright, and smooth skin of these patients did not show the abnormal vascular reactions.

Several investigators have already pointed out that it is the affected skin of atopic patients that exhibits white dermographism,[2-8] pallor reaction to nicotinic acid ester,[5] and delayed blanch with methacholine.[2-9] But others have reported that the abnormal vascular reactions occur in both the involved and uninvolved skin of these patients.[10-12] The difference of opinions might be due largely to the difficulty to define the "uninvolved skin" of patients with atopic dermatitis. To our knowledge, there is no universally accepted concept of the uninvolved skin of this disease. But it is generally agreed that the skin manifestation of atopic dermatitis consists of eczematous patch, lichenified plaque, and prurigo.[13,14] Therefore, the uninvolved skin may be defined as areas of skin where the three types of skin lesion are absent. On the basis of this concept, in the present study we classified the uninvolved skin of atopic dermatitis into two categories, ie, the bright and smooth skin and the sallow and dry skin. Then, it became evident that the sallow and dry skin almost constantly yielded the paradoxic vascular reactions to mechanical stroking and topical application of thurfyl nicotinate or methacholine. This sallow and dry skin histologically showed an eczematous change in the surface epidermis or in the follicular epidermis. The histologic change of follicular wall resembled that of "follicular eruptions" of atopic dermatitis.[15] Thus, it appears evident that the sallow and dry skin is a manifestation of eczematous inflammation of atopic dermatitis, although this dry skin has been included with the stigmata of unaffected skin of the disease.[16] It is therefore most reasonable to consider that patients with atopic dermatitis show the abnormal vascular reactions only in their skin sites where an eczematous change exists.

The present study also demonstrated that the lichenified skin of patients with allergic contact dermatitis constantly produced white dermographism, nicotinic acid blanching, and delayed blanch with methacholine, while the normal skin of these patients did not show the abnormal vascular reactions. This strongly suggests that all these paradoxic vascular responses can occur over areas of skin with eczematous change of a different cause. We therefore believe that the white dermographism, nicotinic acid blanching, and delayed blanch with methacholine seen in atopic dermatitis are secondary phenomena that may give no definite information concerning the diagnosis of this disease.

Elastosis Perforans Serpiginosa Induced by Penicillamine

Electron Microscopic Observations

Nevelle Kirsch, MD, Peter B. Hukill, MD

• **A patient with Wilson disease, under prolonged treatment with penicillamine, developed lesions of elastosis perforans serpiginosa (EPS). Examination of biopsy specimens by light microscopy revealed the characteristic changes of EPS. Examination by transmission electron microscopy revealed structural changes in the elastic fibers not previously described. The appearance of the lesions by scanning electron microscopy is described for the first time. It is suggested that penicillamine induced EPS may be morphologically distinct from the idiopathic form.**

(*Arch Dermatol* 113:630-635, 1977)

Elastosis perforans serpiginosa (EPS) is a skin disease manifested by keratotic papules in an annular or serpiginous pattern. Often the annular lesions tend to spread peripherally, leaving atrophic and sometimes hypopigmented skin in the center. The basic histological defect seems to be a localized abnormality of dermal elastic fibers, which increase in size and number and penetrate the epidermis, where they fill a tract or canal that extends to the surface, allowing the fibers to be extruded from the body. The abnormal elastic fibers in the dermis also incite an inflammatory response, sometimes polymorphonuclear, but often characterized by granulomas that may contain giant cells actively phagocytozing and destroying the injured elastic material.[1]

The disease was first described by Lutz[2] in 1953, and as further defined by Miescher[3] and others,[4] it is generally accepted as a distinct clinical and pathological entity. Although it most often appears as an isolated lesion, about one fourth of reported cases of EPS have been associated with generalized systemic disorders, such as Down syndrome (mongolism), or with specific connective tissue defects, including the Ehlers-Danlos syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, Marfan syndrome, and cutis laxa.[1-5] The lesions may be confined to one anatomic area, often the neck, sometimes the extremities, but disseminated lesions have been described.[6]

Elastosis perforans serpiginosa has been reported in four patients under treatment with penicillamine for Wilson disease,[7,8] but it has not been reported associated with untreated Wilson disease. Penicillamine has been associated with a variety of other skin changes, including hemorrhages and easy bruising, allergic eruptions, milia, peeling and desquamation, cheilosis, stomatis, glossitis, and vulvar ulcers.[8-10] It has also been held responsible for an instance of congenital diffuse connective tissue defect in an infant whose mother received penicillamine during pregnancy,[11] and for a case of cutis hyperelastica.[12] Therefore, it would appear very likely that penicillamine either directly or indirectly produces the lesions of EPS. Assuming that penicillamine does in fact produce the EPS lesion, it appears that study of the effects of the drug might shed light on the pathogenesis of EPS in general and perhaps on other elastic and connective tissue disorders.

Wilson disease, or hepatolenticular degeneration, is an inborn error of metabolism, characterized by accumulation of excessive amounts of copper in the brain, the liver, and other tissues, leading to progressive neuro-

logic deficits and to cirrhosis. Serum copper is low, while copper absorption, as well as urinary excretion are elevated. It would appear that the basic defect is a deficiency in an enzyme that facilitates the binding of copper to the plasma copper-binding protein, apoceruloplasmin. Thus, plasma free copper is high and is transferred to the tissues in unrestricted amounts.[13] Penicillamine is a chelating agent that binds copper and is excreted in the urine. Its administration to patients with Wilson disease will deplete the excessive copper deposits and arrest the progress of the disease.

REPORT OF A CASE

This 22-year-old man first consulted the senior author for a dermatologic problem in June 1972. The patient stated that he had noted the onset of an eruption in 1971, mostly confined to the sides of his neck and back. The lesions were asymptomatic with only very infrequent, mild pruritus. The skin lesions had slowly evolved over the preceding year.

Dermatological examination on his initial office visit showed multiple lesions on the sides of the neck, the anterior portion of the neck, and the nape of the neck, consisting of keratotic papules, both discrete and in linear and arcuate patterns (Fig 1). The surrounding skin was normal in appearance. In July 1972, there was noted the appearance of a single, red, firm papule on the glans penis, which has slowly and progressively enlarged to form a ringed lesion.

The patient was again seen in September 1972, at which time there was noted a red, macular, and irregular patch of redness that was firm to the touch on the right side of the glans penis.

In August 1974, there was progression of the lesion on the penis, which now measured about 2 cm in diameter. At this examination, there was a discoid, firm bordered, elevated lesion with a central depressed area, and within the inner margin of the hyperkeratotic ring, there was a semicircular area of ulceration (Fig 2).

The patient had known Wilson disease since 1958 when he was 9 years old. At that time, he had an enlarged liver, dystonic facies, dysarthric speech, and dystonic posturing of the right upper extremity. Oral administration of penicillamine was started, at a dosage of 1 gm per day. After several months the dose was increased to 2 gm per day and maintained at that level for several years.

The patient was seen for a follow-up examination by his neurologist in April 1965, at which time his main complaint was easy bruising over the extensor surfaces of the elbows and knees on very mild trauma. The patient stated that the bruises persisted for at least a few weeks after mild contact. At that time, the hepatic status was stable, and slight neurological improvement had been achieved with penicillamine therapy, 2 gm per day, but the patient was very concerned about the ecchymotic skin lesion from a cosmetic point of view. The neurologist was reluctant to change the apparently successful regimen and treatment of a serious illness for merely cosmetic reasons. However, since the skin lesions appeared to some extent dose related, it seemed acceptable to try to decrease the dose to 1.5 gm of penicillamine per day.

A further report from the neurologist in July 1972, showed that the patient was taking penicillamine in a dosage that varied from 1.5 to 2 gm per day. He had noted some easy bruising, but had not developed any large ecchymoses at this time. The neurologist advised that the patient continue to take 2 gm of penicillamine daily, and pyridoxine hydrochloride, 50 mg a day, until he returned at a later date for follow up.

Biopsy specimens were taken from the neck lesions on July 11, 1972 and on Jan 10, 1975. The latter was examined electron microscopically.

Light Microscopic Findings

Both biopsy specimens showed simi-

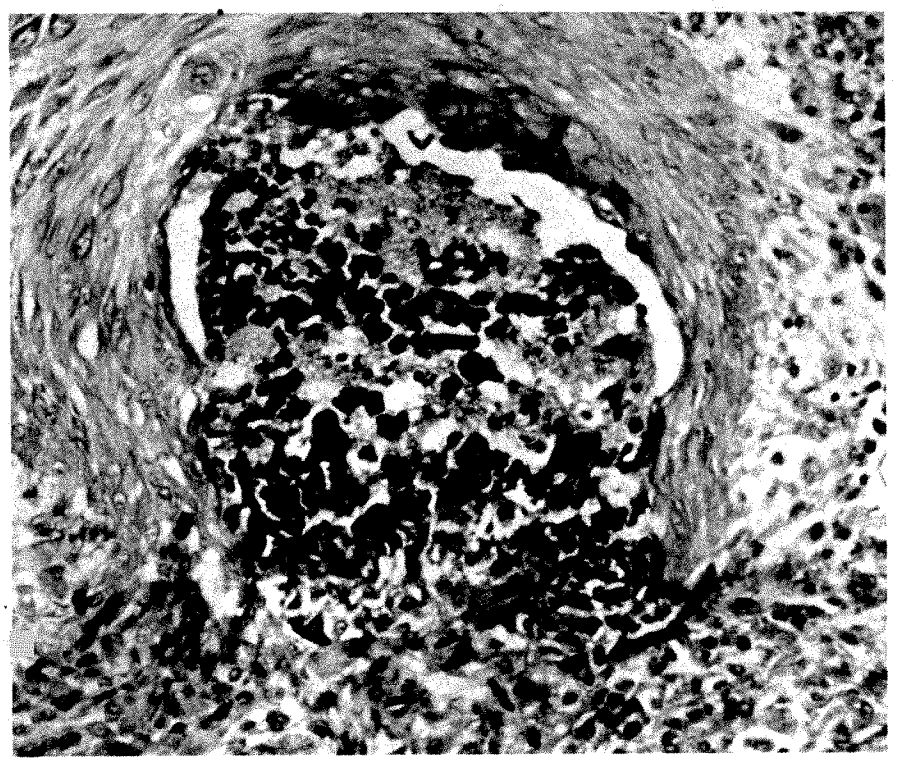

Fig 3.—Pathognomonic lesion of elastosis perforans serpiginosa. Coarse eosinophilic elastic fibers are found within the epidermis (hematoxylin-eosin, green filter, original magnification ×200).

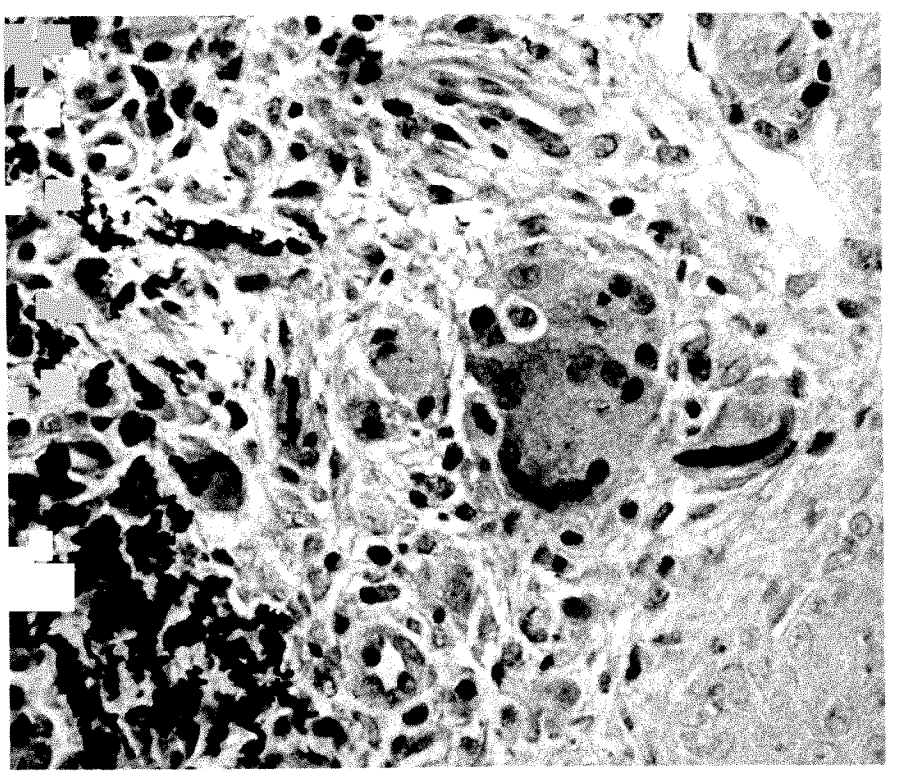
Fig 4.—Granulomatous reaction in reticular dermis. Note coarse elastic fibers with serrated borders at left. Fibers are sparse within granuloma, possibly destroyed by granulomatous process. An elastic fiber is seen at right within cytoplasm of giant cell (Verhoeff-van Gieson, original magnification ×400).



lar changes. Sections stained with hematoxylin-eosin and by the Verhoeff–van Gieson (EvG) method for elastic fibers were available for examination. The epidermis showed a localized area of acanthotic thickening, which was perforated by a canal leading from the dermis into the Malpighian layer. The canal contained granular, basophilic debris, necrotic cells, and large, tortuous, and strikingly eosinophilic fibers (Fig 3). Although eosinophilic, the fibers reacted in the manner of elastic fibers in the EvG stained sections. Near the surface, the canal also contained parakeratotic keratin.

In the underlying papillary dermis, there were increased numbers of unusually coarse elastic fibers, associated with a granulomatous reaction characterized by fibroblastic proliferation, histiocytic infiltration, and multinucleated giant cells of the foreign body type, many of which contained fragments of elastic fibers within their cytoplasm. The reticular dermis contained considerably increased numbers of coarse elastic fibers, only focally associated with a granulomatous reaction. A conspicuous feature of the coarse elastic fibers was their serrated, sawtooth-like borders (Fig 4).

Transmission Electron Microscopic Findings

The tissue was fixed in buffered 10% formalin, transferred to cacodylate buffer, postfixed with osmic acid, and embedded in an epoxy resin. Sections were cut at about 600 A thickness and stained with uranyl acetate and lead citrate. They were examined in an electron microscope (Philips EM-300).

Throughout the reticular dermis, the elastic fibers in the present case were considerably larger in caliber than those in control material. The fibers averaged about 40,000 A (4 μ) in diameter, whereas elastic fibers in our control reticular dermis averaged about 20,000 A (2 μ) in diameter. They consisted of a distinct inner core, or medulla, an outer cortex, and a dense, fibrillar cuticular border. The inner core closely resembled, in size and in structure, normal elastic fibers. It

consisted of fine, skeletal fibrils, oriented parallel to the length of the elastic fiber, embedded in a moderately dense amorphous or finely granular matrix (Fig 5, top). The fibrils were 200 to 600 A in thickness; they showed no obvious periodicity or striations. The outer cortex consisted entirely of matrix material similar to that found among the fibrils in the medulla. The homogeneous cortical layer was not uniform in thickness but was irregularly serrated, ranging in thickness from 5,000 to 20,000 A (0.5 to 2 μ). The bumpy, irregular cortex appeared to correspond to the serrated outline of the elastic fibers as observed in the EvG stained paraffin sections.

The surface of the elastic fibers in EPS was not marked by any discernible membrane; instead it was marked by numerous fibrils about 200 A in diameter. These often showed periodic cross banding or beading with a period of about 150 A, and resembled protocollagen filaments.

Scanning Electron Microscopic Findings

Tissue that had been embedded in paraffin for light microscopy was deparaffinized with xylol and taken through alcohol to water. It was then incubated in 0.05% bovine testicular hyaluronidase buffered to pH 5 at 37 C for two hours to remove ground substance. The tissue was then dehydrated with absolute acetone and dried with CO_2 by the critical point method. The tissue was shadowed with gold, and examined with a scanning electron microscope. The surface examined was that produced by the microtome knife in cutting the paraffin sections, and thus closely corresponds to that seen in the light microscopic slides.

Atypically large fibers, doubtless corresponding to the large elastic fibers seen in the EvG preparations, were easily found in the papillary dermis adjacent to the epidermal perforation. These fibers appeared to extend through the epidermal basement membrane below the epidermal perforating canal. They were seen not only in the lumen of the canal, but also in the interstices of the keratinocytes adjacent to the canal (Fig 6). Occasionally, they appeared to penetrate the cytoplasm of the cells and destroy them.

Fig 5.—Transmission electron micrograph of dermal elastic fiber, from EPS (top), compared to elastic fiber from normal dermis (bottom). Inner core of fiber from EPS closely resembles normal fiber. Surrounding it there is homogeneous cortex. Surface is intimately related to numerous fibrillar structures (top and bottom, original magnification, ×18,000).

COMMENT

Our observations made by light microscopy are generally similar to those described previously in cases of EPS, both idiopathic and penicillamine associated.

Especially notable in our material was the intense eosinophilia of the elastic fibers penetrating the epidermis, while those in the reticular dermis were either eosinophilic or basophilic. The eosinophilia has been noted before[6,14] but seldom emphasized. It has also been noted[15] that elastic fibers may be eosinophilic in early actinic elastosis, later becoming basophilic.

The rough, serrated, sawtooth-like outlines of the enlarged elastic fibers noted in the Verhoeff preparations of our material have not previously been described. At first we were inclined to ascribe it to artifact, until the electron micrographs confirmed its presence. This irregular structure was conspicuous by light microscopy in both biopsies. We have not observed this serration in other cases of EPS recently examined, none of which

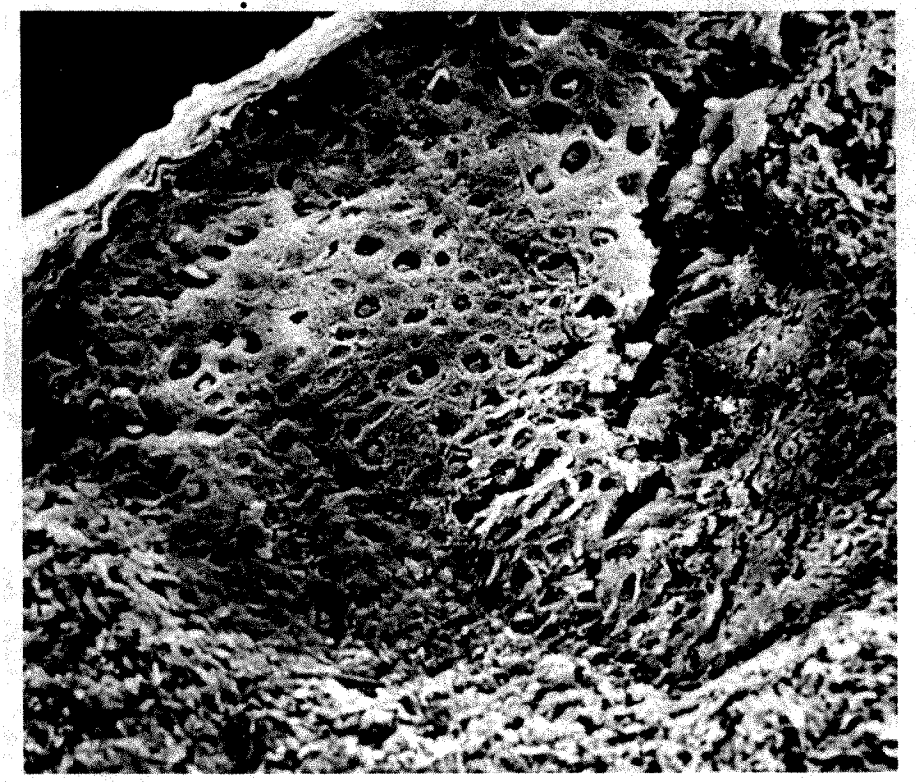


Fig 6.—Scanning electron micrograph. Elastic fibers (white) can be seen in interstices between keratinocytes adjacent to intraepidermal canal (×800).

were associated with penicillamine. Possibly this change is unique to the lesion induced by penicillamine.

The electron microscopic finding in EPS have been described in three cases, none penicillamine induced. Cohen and Hashimoto,[14] using osmium fixed, methacrylate embedded but unstained sections, noted that the Verhoeff–positive material was amorphous without periodic striations and resembled normal elastic fibers. It is apparent that the unavailability of heavy metal staining at the time of their report did not allow observation of structural subtleties. Hashimoto[16] later described the fine structure of the elastic fibers in EPS and compared it to their structure in normal skin as well as other pathologic conditions. He noted that the dense elastic matrix substance was deposited not only on protofilaments, as in normal skin, but also on reticulum fibrils and collagen fibers in the papillary dermis. He neither described nor illustrated the outer cortex of structureless matrix material overlying the central, fibril-containing core seen in our case. Subsequently, Hashimoto and Kanzaki[17] have reinterpreted the dense material within the fibers as an amorphous granular material ("dense bundles") rather than as microfibrils and have described the ultrastructural alterations in cases of cutis laxa not related to penicillamine therapy.

More recently, Meves and Vogel[18] described in detail the ultrastructural changes in a case of idiopathic EPS. They described and illustrated increased number of elastic fibers of large caliber, convoluted and branching. On the surface of the fibers, they described numerous fine filaments which they noted were similar to those seen in normal embryonic elastic fibers and interpreted as being newly formed. They also emphasize reduplications and discontinuities in the epidermal basement membrane in the area of perforation. They neither describe nor illustrate the peripheral, fibril-free cortex of the elastic fibers seen in our case.

The pathogenic mechanism of EPS in general is unknown, and how penicillamine initiates these mechanisms is equally unknown. Normal elastic fibers by transmission electron microscopy appear to be composed of a skeleton of delicate fibrils, resembling collagen or precollagen, which are embedded in a dense homogeneous matrix.[16] Only the matrix material is susceptible to elastase, the fibrils being resistant.[19] Properly then, only the homogeneous matrix material should be designated *elastin*. The penetration of elastic fibers into the epidermis and their subsequent extrusion onto the surface is apparently unique to EPS. However the accumulation of neutrophils and the formation of granulomas with phagocytosis are not unique. Phagocytosis of elastic fibers is prominent in actinic granulomas[20] and has been noted in healing wounds. It has been produced experimentally by implantation of bovine elastin subcutaneously in rats,[21] and by degrading vivo vascular elastic fibers by injecting pancreatic elastin into the carotid arteries in rabbits.[22] It would appear that injured or foreign elastic tissue regularly in vivo incites a polymorphonuclear response, followed by a granuloma that phagocytizes and effectively removes the elastic material.

It has been known for some time that copper deficiency produces vascular disease and changes in the elastic tissue in swine.[23,24] Waisman and Carnes[25] produced copper deficiency in swine and noted that the internal elastic lamina of the coronary arteries became fragmented and thinned. Electron microscopy demonstrated fenestrations and eventual fragmentation of the fibers. They believe that copper is necessary for the formation of cross-links between fibrils of the elastic precursor.

Simpson and Harms[26] also examined by electron microscopy the vascular lesions of copper deficient chicks. They found dissolution of matrix of elastic fibers, with persistence of the skeleton fibrils. The elastic tissue changes seen in experimental copper deficiency are not identical to those reported in human EPS nor do they closely resemble changes in our own material.

Because it is established on an experimental basis, that copper is neces-

sary for normal elastic tissue formation, and because it is known that penicillamine is capable for depleting tissues of copper, it is tempting to hypothesize that EPS, at least in penicillamine induced cases, is due to depletion of copper.

However, there is good evidence that Menke kinky hair syndrome is primarily due to a defect in copper absorption, and that all its clinical manifestations are caused by tissue copper deficiency.[13] Notably, the histologic changes seen in the elastica of vessels[27] closely resemble those produced experimentally in copper deficient animals.[25] But patients with Menke syndrome do not develop the clinical changes of EPS nor do they get the elastic tissue changes observed by us. Therefore, it is suggested that EPS may be due to deficiency of another trace metal that is bound by penicillamine.

Our observations in the single case of penicillamine induced EPS are different from those previously described by others,[16-18] and different from our own observations in a case of EPS associated with Down syndrome. If examination of further cases of penicillamine-induced EPS confirms that the appearance of the elastic fibers is constantly different from their appearance in idiopathic EPS, it would suggest the penicillamine-induced lesion arises through a different pathogenetic process. Possibly, the clinical (and light microscopic) picture of EPS, as well as other granulomatous and perforating elastoses, is the final tissue reaction to a variety of injuries to elastic fibers. In penicillamine-related cases, the injury may be due to deficiency of copper or other trace metal, while the injury to the elastica may be qualitatively different and arise through an entirely different mechanism in idiopathic cases. It is hoped that examination of further cases by electron microscopy, together with tissue assay for trace metals will shed some light on the problem.

Immunoblastic Lymphadenopathy With Purpura and Cryoglobulinemia

Harry L. Wechsler, MD, Alexander Stavrides, MD

• **Immunoblastic lymphadenopathy is a recently described lymphoproliferative disorder, presumably of B-cell origin. It is characterized by regional or generalized lymphadenopathy, usually associated with hypergammaglobulinemia or dysproteinemia. Other findings may be hepatosplenomegaly, dermatitis, fever, malaise, weight loss, and various altered immunologic reactions. Histologically, the involved lymph nodes show immunoblast, plasmacytoid, and plasma cell proliferation. This may be extranodal as well.**

The case reported here is one of the few followed up prospectively. The patient's purpuric eruption was an apparent manifestation of a type II mixed cryoglobulinemia. Differing from what has usually been reported, we noted hypogammaglobulinemia and findings in part of altered cell-mediated immunity. Despite leukopenia and anemia there were no infectious episodes. Although a satisfactory treatment regimen has not been established, there was beneficial response to prednisone and short courses of melphalan.

Recent retrospective clinical and pathologic studies have suggested the existence of a lymphoproliferative disorder separate and distinct from malignant lymphoma, with which it had been grouped. This syndrome has been referred to as angioimmunoblastic lymphadenopathy with dysproteinemia,[1] immunoblastic lymphadenopathy (IBL),[2] lymphogranulomatosis X[3], and immunoblastic lymphadenopathy with mixed cryoglobluinemia.[4] The characteristic findings are nodal immunoblastic proliferation, apparently of B-cell origin, associated with or giving rise to elevated γ-globulin levels.[1-3,5,6] The clinical course is characterized by lymphadenopathy usually with hepatosplenomegaly, weight loss, fever and sweating, and a nonspecific dermatitis. A usual feature has been hypergammaglobulinemia of a polyclonal type but, on occasion, also monoclonal. Cryoglobulins have been identified as the responsible paraproteins in a few of the cases.[2-4] Histologic changes in the lymph nodes are quite characteristic, consisting of proliferation of immunoblasts, plasmacytoid lymphocytes, and plasma cells; prominence and arborization of small vessels; and interstitial deposition of eosinophilic material.[1-3] These may be extranodal as well. Since only a limited number of cases have been observed, the course of the disease has been unpredictable. Spontaneous remission has been noted in some patients who did not have treatment. On the other hand, rapid termination has occurred in others in spite of treatment. A frequent complication has been recurrent infections, which accounted for the death of seven patients in one series.[1] This has prompted Rappaport and Moran[5] to suggest that if therapy is undertaken, cytotoxic agents may be contraindicated and that a corticosteroid should be the drug of choice. Lukes and Tindle,[2] in a review of their autopsy findings, noted frank neoplastic change in three of the cases that they diagnosed as immunoblastic sarcoma. However, most observers do not regard IBL to be a malignant lymphoma. Frizzera et al[1] and others[2] have suggested that clinically and histopathologically the process resembles a graft-vs-host reaction. Some investigators, because of the history of chronic drug and chemical exposure in some of the patients, have proposed that the cause of the disease is due to chronic antigenic stimulation.[2-4]

The case reported here afforded one of the few opportunities to follow up

Fig 1.—Purpura of legs in 53-year-old patient.

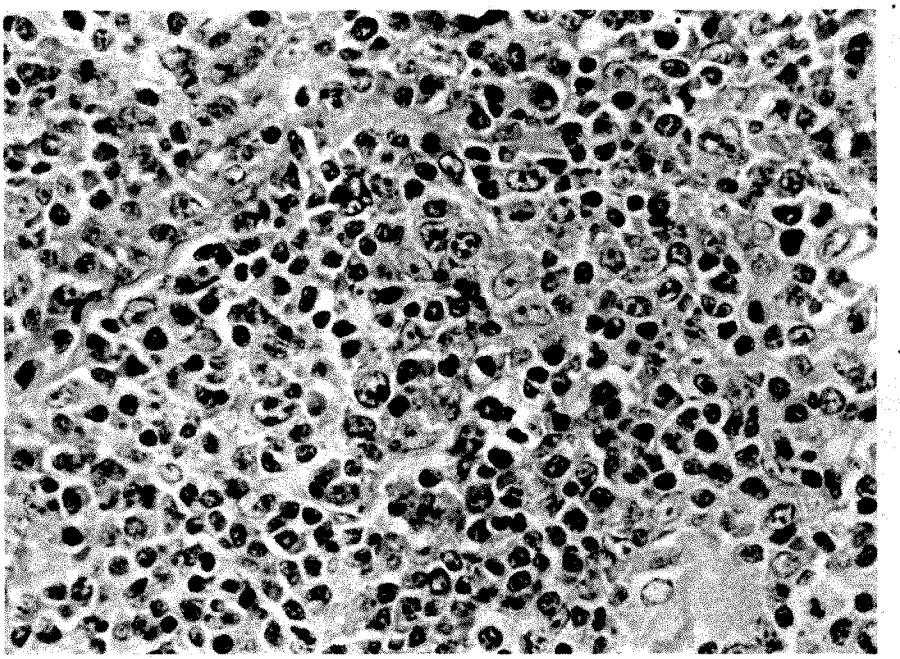

Fig 2.—Pleomorphic infiltrate composed of immunoblasts, lymphocytes, and plasma cells. Deposits of amorphous eosinophilic material (hematoxylin-eosin, original magnification ×240).

the course of the disease in a patient for whom the diagnosis had been established beforehand.

REPORT OF A CASE

A 53-year-old woman was admitted to the Western Pennsylvania Hospital Jan 6, 1975, because of progressive left cervical lymphadenopathy of three months' duration. Petechiae of the lower extremities were present for two months (Fig 1). The eruption was pruritic, first appeared about the ankles, then spread proximally to involve the buttocks. Histologic examination of a nodal biopsy specimen at a neighboring hospital showed "chronic inflammation." Bone marrow and toxoplasmosis studies were reported to be negative. The patient denied malaise, weight loss, or weakness. She did complain of discomfort, tightness, and pain in the calves of the legs on walking. There was no history of exposure to chemicals or oral or parenteral administration of drugs, vitamins, or both.

Physical examination showed an obese woman in no apparent distress. Lymphadenopathy of the left anterior and posterior cervical chains was prominent, including a large mass over the parotid area, giving a lump-jaw-like appearance. The nodes were discrete, varying in size from 0.5 to 3.0 cm. There were bilateral moveable axillary nodes about 2.0 to 3.0 cm in diameter, and those of the inguinal area were shotty.

An erythematous nonblanching macular eruption, 3 to 5 mm in diameter, with central punctate hemorrhage involved the lower trunk and lower extremities (Fig 1). There was no hepatosplenomegaly.

Initial Laboratory Studies

Initial laboratory findings showed the following: hemoglobin, 10.2 gm/100 ml; hematocrit, 30%; WBCs, 4,100/cu mm, with 75% neutrophils, 11% lymphocytes, and 14% monocytes; platelets, 171,000/cu mm; and reticulocyte count, 1.8%. The peripheral blood film showed mild anisocytosis. Erythrocyte sedimentation rate at room temperature was 60 mm/hr in the first hour (Westergren). Serum iron level was 36 μg/100 ml (normal, 65 to 150 μg/100 ml); total iron binding capacity was 190 μg/100 ml (normal, 250 to 420 μg/100 ml). Haptoglobin value was 260 mg/100 ml (normal, 30 to 210 mg/100 ml). Serum protein level was 5.9 gm/100 ml; albumin, 3.1 gm/100 ml; and globulins, 2.8 gm/100 ml. The remainder of the results from automated blood chemical analyses were within normal limits.

Results of a direct Coombs test were negative. The VDRL and rapid plasma reagin test findings were nonreactive. Determinations for antinuclear, parietal cell, mitochondrial, smooth muscle, and thyroglobulin antibodies were negative.

Latex agglutination (rheumatoid arthritis factor) was positive 1:5,120. Toxoplasmosis antibodies by the passive microhemagglutination technique were positive 1:64. The Sia water test result was positive; heterophile antibodies, negative.

Histopathologic Findings

Microscopic sections were reviewed of two left cervical lymph node specimens taken at biopsies performed at another institution three months previously. Histologic examination of sections stained with hematoxylin-eosin and Foot reticulin showed extensive distortion of the normal lymph node architecture. Normal lymphoid follicles with germinal centers and medullary sinuses were rarely observed. There was a diffuse proliferation of immunoblasts, plasma cells, plasmacytoid lymphocytes, and histiocytes. There was an increased number of small blood vessels.

Biopsy specimens of cervical lymph nodes were obtained shortly after admission. The material consisted of a mass of matted lymph nodes, the largest of which was 1.5 cm in diameter. Histologic examination of sections stained with hematoxylin-eosin, Foot reticulin, methyl green-pyronine, Giemsa, and PAS showed diffuse alteration of the normal architecture. There was a mixed cellular proliferation of large immunoblasts and plasma cells (Fig 2). Distinct lymphoid follicles were not present. The immunoblastic cells had large round or oval nuclei with dispersed chromatin and one to two prominent basophilic nucleoli (Fig 3). These were surrounded by a thin rim of pyroninophilic cytoplasm. There was an increase in the number of blood vessels, which had prominent endothelial cells (Fig 4). Small quantities of amorphous, acidophilic interstitial material

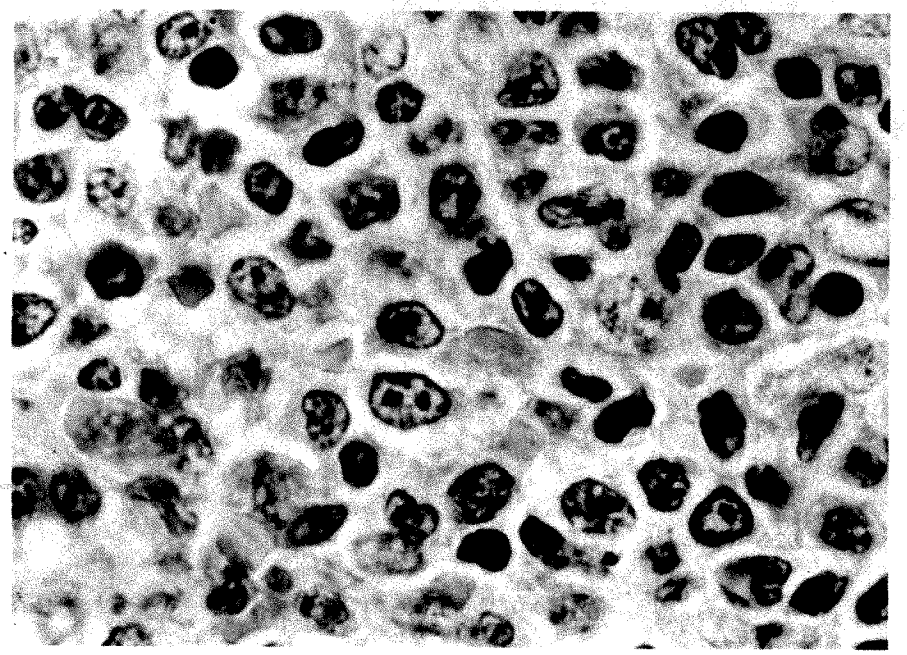

Fig 3.—Numerous immunoblasts having round or oval nuclei with dispersed chromatin, prominent one to two basophilic nucleoli, and thin rim of cytoplasm. Few plasma cells and plasmacytoid cells are seen (hematoxylin-eosin, original magnification ×600).

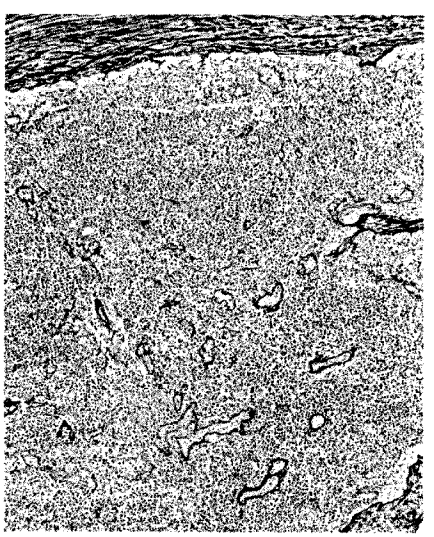

Fig 4.—Increased number of arborizing blood vessels (reticulin stain, original magnification ×90).

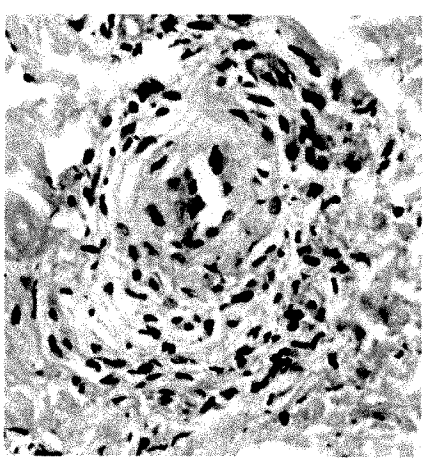

Fig 5.—Small arteriole showing swelling of endothelium and fibrinoid degeneration of wall surrounded by polymorphonuclear leukocytes, some of which are undergoing nuclear fragmentation (hematoxylin-eosin, original magnification ×600).

were noted (Fig 2). Small clusters of four to five histiocytic cells forming sarcoid-like nodules were seen.

Material from a biopsy specimen of a purpuric lesion of the leg was divided in two. Half was routinely fixed in formaldehyde solution and the other half quickly frozen and cut on a cryostat for immunofluorescent studies.

Histologic examination of sections stained with hematoxylin and eosin showed in the upper dermis degeneration of capillaries and small arterioles with disruption and swelling of the endothelium. Many polymorphonuclear leukocytes showed fragmentation of the nuclei and nuclear dust characteristic of leukocytoclastic angiitis (Fig 5).

Direct immunofluorescence of frozen sections of the skin, processed by standard procedure using monospecific human immunoglobulin, complement C3, and fibrinogen antisera, showed the presence of IgG, IgM, and C3 deposits in the wall of the blood vessels.[8] Fibrin was noted on and around the wall of the blood vessels.

Bone marrow biopsy showed a hypercellular bone marrow. The myeloid to erythroid ratio was 3:1. Megakaryocytes were normal. Plasma cells, plasmacytoid lymphocytes, and immunoblasts were noted in small numbers. The iron stores were depleted.

Immunologic Studies

Serum immunoglobulins and complement components C3 and C4 were determined by the radial immunodiffusion technique.[9]

Findings on admission were as follows: IgG 335 mg/100 ml (normal, 590 to 1,310 ± 2 SD); IgA, 183 mg/100 ml (normal, 80 to 200 ± 1 SD); IgM, 702 mg/100 ml (normal, 90 to 170 ± 1 SD); C3, 66 mg/100 ml (normal, 123 to 167); and C4, 5 mg/100 ml (normal, 20 to 50). Repeated studies showed progressive reduction of IgM, persistence of hypogammaglobulinemia, and return of C3 to normal levels (Fig 6).

Serum protein electrophoresis was performed on cellulose acetate and immunoelectrophoresis on agarose gel.[10] It showed on admission a small spike in the γ region, suggesting a monoclonal gammopathy. This was absent on repeated serum electrophoretic studies at three, six, and nine months (Fig 6).

Agarose gel immunoelectrophoresis of the serum showed an increase of the IgM fraction and a monoclonal gammopathy of IgM-κ specificity. Bence-Jones protein in urine (determined after fiftyfold concentration of the urine and by immunoelectrophoresis in agarose gel and diffusion against κ and λ light chains) was absent.

Cryoglobulin determination after drawing blood with prewarmed syringe and needle was performed by separating the serum from the blood, and allowing it to clot for 60 minutes at 37 C. The cryoglobulins were precipitated and isolated for immunochemical studies at 4 C. The cryocrit level was determined by the method of Peetom.[11]

On initial examination the cryocrit level was 13%. The protein concentration in the cryoglobulin precipitate was 1.4 mg/ml. By immunoelectrophoresis, the cyroglobulins were found to be mixed cryoglobulins of IgG-IgM type. All the rheumatoid factor activity was present in the cryoprecipitate without any detectable rheumatoid factor activity in the supernatant. The immunoglobulin Ig concentration in the cryoglobulins was IgG, 0.5 mg/ml, IgM, 0.7 mg/ml. There was a progressive reduction in the cryocrit and cryoglobulin concentrations during the course of treatment (Fig 6).

Peripheral blood T and B lymphocytes

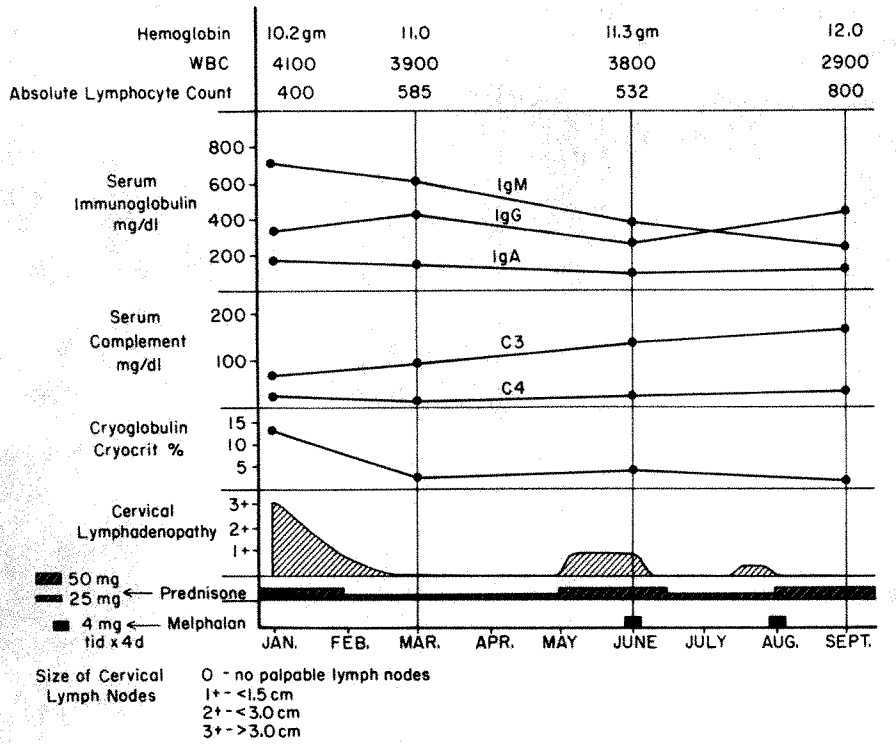

Fig 6.—Laboratory and clinical response to treatment.

were determined by separating lymphocytes from whole heparinized blood by the density gradient centrifugation technique of Böyum.[12] The sheep erythrocyte rosette assay for T lymphocytes was performed by a modification of the procedure of Jondal et al.[13] Surface immunoglobulins for B lymphocytes were detected by standard procedures, using fluorescein-conjugated polyspecific antihuman immunoglobulin fluorescein to protein (5.8) ratio.[14]

Findings on admission were WBC, 4,100/cu mm; lymphocyte count, 450/cu mm; T lymphocytes, 42% (normal, 60% to 70%); and B lymphocytes, 10% (normal, 20% to 30%). Two months later, WBC was 3,200/cu mm; lymphocyte count, 620/cu mm; T lymphocytes, 49%; and B lymphocytes, 46%.

Cell-mediated immunity studies were performed. Blastogenic transformation of lymphocytes to phytohemagglutinin (PHA) stimulation was determined by a microtechnique using heparinized whole peripheral blood. The incorporation of tritiated thymidine into DNA was measured and the stimulation index (SI) calculated as the ratio disintegration per minute (dpm) + mitogen/dpm – mitogen.[15]

On admission, the blastogenic transformation by PHA (SI) was 39 (normal, 60 to 200). Two months later, the SI was 33.

Mumps virus vaccine, Candida albicans, and tuberculin were injected intradermally. The mumps site was positive after 24 hours. There were no reactions at the other sites.

Sensitization to 2.04-dinitrochlorobenzene (DNCB) was attempted by applying 0.05 ml of a 1.0% solution in acetone to the volar aspect of the right forearm. Erythema was apparent in 24 hours. Challenging dose of DNCB of 0.05 ml of 0.1% solution applied to the volar aspect of the left forearm three weeks later failed to produce a reaction. During this time the patient had been taking prednisone, 50 mg/day.

Course

After the initial workup the patient was placed on a regimen of prednisone, 50 mg/day. There was prompt dramatic clearing of the purpura and substantial reduction in the size of the nodes. The patient was discharged after two weeks of hospitalization. Her condition remained well controlled for about five months, while she received prednisone, 25 mg/day. When the dose was changed to alternate daily administration, the purpura recurred. After about six months, cervical adenopathy reappeared. It persisted despite increasing the dose of prednisone to 50 mg/day. A short course of melphalan (Alkeran), 4 mg three times daily for four days, produced prompt resolution. This was successfully used again during lymphadenopathy at eight months. Allopurinol, 300 mg/day, and later 150 mg/day, was given during the patient's course. Other than mooning of the face and weight gain, the patient physically appeared to be normal.

In December the patient developed an acute respiratory infection manifested by spiking fever, chills, and dyspnea. Roentgenogram of the chest showed a diffuse infiltrate bilaterally. *Staphylococcus aureus* coagulase was cultured from the sputum. There was an accompanying rise in the cryocrit level to 13%.

The patient was hospitalized and treated with oxacillin, 250 mg four times daily, for a period of ten days. The fever and symptoms were reduced. A lung biopsy specimen was obtained by fiberoptic bronchoscopy. However, the tissue showed no pathologic change; cultures for bacteria, fungus, and virus were negative. Cytomegalovirus was cultured from the nasopharynx and urine. Otherwise, the patient's course has been maintained on varying doses of prednisone and allopurinol. There has been no important change in the chest roentgenogram after eight weeks.

The patient remained active and relatively well until June 1976. She then developed fever, malaise, leg cramps, and marked dyspnea but no demonstrable lymphadenopathy. A progressive deterioration in her condition was characterized by rapidly enlarging necrotizing ulcers of the left leg associated with local and systemic infections only temporarily abated by antibiotic therapy. A recalcitrant thrombocytopenia (platelet count ranged from 20,000 to 50,000/cu mm) was not altered by increasing prednisone to 75 mg daily and splenectomy. The hypoimmunoglobulinemia G became more severe; values ranged from 14 to 36 mg/100 ml. The last five days of her life there was frank hemoptysis and melana. Despite transfusions with packed red blood cells and platelets, she died Dec 30, 1976.

An autopsy was done. Principal findings were gastrointestinal hemorrhage, stress gastric and duodenal ulcers, necrotizing ulcerative proctitis, and pulmonary abscesses and small thrombi. A polymicrobial septicemia was due to *Escherichia coli* and *Streptococcus faecalis* infection. There was generalized cytomegalic inclusion disease.

Microscopic examination of sections of enlarged paraortic lymph nodes showed the characteristic findings of IBL as did the spleen that was removed surgically one month prior to death.

COMMENT

Evidence presented to date strongly supports the concept that IBL is a distinct entity or syndrome, the histologic measurements of which have been well established.[1-3] Since most of

the data has been collected retrospectively, the spectrum of clinical and laboratory variables has been incompletely defined.

In this case, one of the few prospective studies reported, the patient was without some of the so-called cardinal clinical features such as hepatosplenomegaly and hypergammaglobulinemia. Neither was there any history of fever, weight loss, or fatigue. Besides the regional bull-neck type of lymphadenopathy, the only other physical abnormality was the nonpruritic purpuric eruption involving the buttocks and lower extremities. Dermatitis has been frequently noted in IBL, but in most cases has been described as a nonspecific maculopapular eruption with or without pruritus.[1] In isolated instances, it has been urticarial or purpuric. Evidence suggests that in our patient the purpuric eruption was a manifestation of dysproteinemia, which in this instance was a mixed cryoglobulin. Supportive of this were the histologic findings of leukocytoclastic vasculitis and the presence of immune complexes. The latter were demonstrated by direct immunofluorescence of biopsy material of a purpuric lesion of a leg. As is characteristic, the immune complexes of IgG and IgM reflected the makeup of the cryoglobulin.[16] Cryoglobulinemia of the mixed type in a patient with IBL has been reported by Schultz and Yunis.[4] They found the cryoprecipitate to consist of IgG, IgM, and IgA. As previously noted, we isolated a mixed cryoglobulin consisting of IgG and IgM. The cryoglobulin was considered to be type II, according to the classification of Brouet et al.[17] The IgM was monoclonal of κ specificity and had an antibody activity directed against the IgG, which was of polyclonal type. This was consistent with the findings of Brouet et al[17] who demonstrated that in mixed cryoglobulinemia, a monoclonal IgM may act as an antibody against a polyclonal IgG. A reflection of this IgM-IgG interaction was the presence in our patient of a rheumatoid factor positive at more than 1:5,000, but absent when the cryoglobulin was removed from the serum. Further reason for classifying the cryoglobulin as type II is that lymphoproliferative disorders are more usually associated with type I or type II whereas autoimmune diseases are associated with type III.[17] The finding of cryoglobulinemia in our patient and in those of Lukes and Tindle,[2] and Schultz and Yunis[4] leads to speculation that if more cases of IBL had been diagnosed prospectively, cryoglobulins may have been found in several of them.

The accumulated data indicate that immunologic abnormalities in IBL vary considerably from case to case, despite the findings of a wide range of aberrant reactions including cryoglobulinemia, lymphopenia, Coombs-positive hemolytic anemia, thrombocytopenia, Bence-Jones proteins, and smooth muscle antibodies; only a few may be present in any one case. Hypergammaglobulinemia was found in most patients and was considered to be a cardinal feature of the disorder.[2] Conversely, hypogammaglobulinemia was present in our patient. Radaszkiewicz and Lennert[3] reported similar findings in several of their cases. Apropos to this situation, it is not unusual in immunoproliferative disorders, such as multiple myeloma where abnormal proteins are elaborated, for there to be a decrease in production and increased catabolism of normal γ-globulins.[18] A persistent finding in our patient was a lymphopenia that did not vary despite therapy. We did not look for lymphocytotoxic antibodies, but Lukes and Tindle[2] alluded to a lympholytic factor being the cause of lymphopenia in one of their cases.

What appears to be well established is the histologic pattern of the lymphadenopathy. The prominence of blood vessels (postcapillary venules) and obliteration of nodal germinal centers by proliferating immunoblasts, plasma, and plasmacytoid cells, which were evident in our patient, have been consistently described in previously reported cases.[1-4] Such an interrelationship of cells has suggested that the lymphoproliferative disorder may be of B-cell origin.[2] We failed to uncover any substantial evidence supporting this proposition. The results of repeated studies to determine circulating B lymphocytes by immunofluorescence and T lymphocytes by sheep-erythrocytes' rosette formation were equivocal. However, there was a somewhat increased percentage of B cells on a follow-up determination. This increase may have been secondary to the steroid therapy.[19] Also, the initial low B-lymphocyte count may have been indicative of circulating immature cells lacking surface immunoglobulins. On the other hand, there is evidence that the function of T lymphocytes may be impaired. Despite response to intradermal injection of mumps in our patient, there was poor lymphoblastic response to PHA and failure to sensitize to DNCB. This has been observed in similar conditions, particularly those involving plasma cell proliferation.[18] There is an ability to retain recognition of antigens previously sensitized to, but an inability to develop response to new antigens. Since the patient had been taking prednisone, it may be contended that this interfered with the mechanism to sensitize to DNCB, but studies both in the laboratory animal[20] and in man[21] have failed to show conclusively that cell-mediated immunity can easily be influenced. Claman[22] in his review states that cell-mediated immunity can be suppressed by corticosteroid therapy, but larger amounts are necessary over an extended period of time.

It has been purported that the development of IBL is due to chronic antigenic stimulation such as that considered in similar lymphoproliferative disorders.[23-25] Several of the patients with IBL had received drugs and therapeutic agents over a period of time.[2-4] No such history was obtained from our patient. Others have suggested the pathogenic mechanism to be a graft-vs-host-type reaction.[1,7]

Proper therapy has not been established. Remission and exacerbation have been reported despite treatment or lack of it. Rappaport and Moran[3] suggested that because of repeated infections, at times leading to death, cytotoxic agents should be avoided. A corticosteroid was suggested by them as the drug of choice. After prompt and dramatic improvement with con-

comitant reduction in the amount of cryocrit and serum IgM while receiving prednisone, 50 mg/day, our patient remained clinically well. It is noteworthy to point out that there had been no infection despite leukopenia with absolute lymphopenia and hypogammaglobulinemia. This was so despite giving prednisone 25 to 50 mg/day along with two short courses of melphalan, which was necessary to negate recurrence of the cervical lymphadenopathy. Our experience suggests that prednisone and judicious use of cytotoxic agents such as melphalan can be therapeutically beneficial.

Immunoblastic lymphadenopathy appears to be a distinctive lymphoproliferative disorder with characteristic clinical, laboratory, and histologic findings. Since dermatitis may be a prominent feature of the condition, the dermatologist may be the first to be sought out by the patient. Therefore, a prompt and correct diagnosis may well be his responsibility.

Nonproprietary Names and Trademarks of Drugs

Lymphocutaneous Nocardiosis Due to *Nocardia brasiliensis*

Eliezer Zecler, MD; Yigal Gilboa, MD; Luba Elkina, MD; Gerald Atlan, MD; David Sompolinsky, PhD

• A farmer had chaining lymphocutaneous granuloma on the right hand and arm. Clinically the syndrome seemed typical for sporotrichosis. Bacteriological examination revealed *Nocardia brasiliensis* as the only etiologic agent. Since 1920, eight similar cases of sporotrichoid nocardiosis have been reported from various parts of the world. To our knowledge, isolation of *N brasiliensis* has not been reported previously in this geographical area.

(*Arch Dermatol* 113:642-643, 1977)

Infections with *Nocardia* may be systemic or localized. Affection of the lungs is most often due to *N asteroides*, and this infection has a tendency to hematogenous spread with multiple far-sited foci. Chronic granuloma of the skin (mycetoma) may be due to either *N asteroides* or *N brasiliensis*, and dissemination is uncommon. However, since 1920, eight cases of nocardial mycetoma advancing along the lymphways have been reported.[1-8] An additional case will be presented here, primarily to bring to attention the possibility of this etiology for a syndrome clinically typical for sporotrichosis.

REPORT OF A CASE

A 64-year-old farmer was seen on Oct 23, 1972, complaining of an indurated, ulcerated pus-producing area, on the second finger of his right hand. He had been working in the field during the preceding weeks, but could not remember any particular trauma to the diseased site.

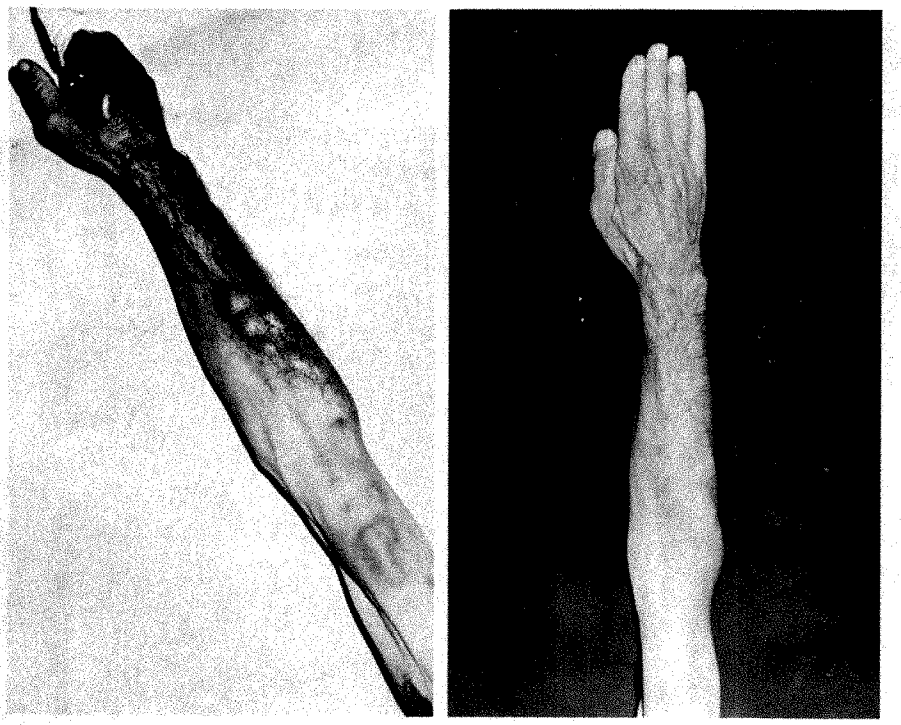
On admission, the body temperature was 37 C. On the dorsal surface of the affected finger, there was a circulated chancroid ulceration, 2 to 3 cm in diameter. Multiple subcutaneous, erythematous nodules, 1 to 4 cm in diameter, were noted as a necklace along the lymphatics on the extensor surface of the right forearm (Figure). These nodes were red, tender and painful. The axillar lymph nodes were also swollen and tender.

No abnormal findings were revealed by ECG, chest roentgenogram examinations, blood counts, blood chemistry (BUN, nitrogen, glucose, electrolytes, liver function tests) and urine examination.

The clinical diagnosis made was sporotrichosis. Treatment with a saturated solution of KI, 15 drops, three times daily, was started. A few days later, when the bacteriological diagnosis was known, sulfadiazine, 4 gm daily, was added. This schedule was continued for two months. The lesions healed gradually in the course of five to six weeks, leaving only superficial scarring. The patient was seen again for followup one year later, and his health was good both subjectively and objectively.

MICROBIOLOGICAL FINDINGS

Pus samples aspirated from two efflorescenses were examined. The material was yellow and turbid but without sulfur grains. Microscopic examination of smears revealed predominantly polymorphonuclear leukocytes and Gram-positive slightly branching filaments with fragmentation, but without coccoid forms. The specimens were inoculated on blood agar, Loewenstein medium, Sabouraud glucose agar with and without chloramphenicol (10 μg/ml) and also into tryptose phosphate broth. Growth was inhibited by chloramphenicol, but could be observed on all drugless media after five to seven days. The colonies were first small and velvety, later they became dry, large, and wrinkled. Colonies on Sabouraud agar were ocher to orange and had a strong earthy odor. Microscopically, the cultured organisms were partially acid fast. In broth cultures, the small,



Left, diseased arm on day of admission, and right, same arm after six week's of treatment.

round, and heavy, whitish to yellowish, colonies adhered strongly to the glass. Growth occurred at both 30 C and 37 C, but not at 46 C.

The following biochemical reactions were observed: decomposition of casein and of tyrosine but not of xanthine and hydrolysis of urea but not of starch. Gelatin was also hydrolyzed and lithmus milk was peptonized without coagulation. After growth in 0.4% gelatin in water, the medium turned alkaline, and ninhydrin reaction was positive. Also in this fluid medium, small colonies developed that strongly adhered to the wall of the test tube. It should be added that acid was formed from glucose and inositol.

Injection of a heavy inoculum of the bacteria, suspended in 1% polysorbate (Tween 80), into the peritoneum of mice, proved fatal in four to seven days. Small bright noduli containing a thick purulent or necrotic material with sulfur granula occurred in the lungs, spleen, liver, and kidneys. By microscopic examination both coccoid, rod-shaped, and filamentous organisms were observed.

On the basis of the morphological, physiological, and pathogenic properties, the organism was identified as *N brasiliensis*.

COMMENT

Geographically, *N brasiliensis* is not restricted to South America. Infections with this organism in North America and Africa have been described. The present case is the first from Israel. The organism belongs to the normal soil flora; in all but one case of sporotrichoid nocardiosis published hitherto, the patients were working in the garden previous to the infection (5 cases) or playing with cats (two cases).

Although the spread of the infectious agent from a primary inoculation site through the lymphatics in a chaining nodular pattern is characteristic of sporotrichosis, a thorough microbiological examination for alternative etiological options should be performed, including the possibilities of tularemia and pseudomycoses due to *Nocardia*.

Eosinophilic Ulcer of the Tongue

Report of Two Cases

Gordon H. Burgess, MD; Amir H. Mehregan, MD; Alan J. Drinnan, MD, DDS

• **Two cases of tongue ulcers are presented. Histopathologic examination of biopsy specimens obtained from each case showed marked submucosal and muscular infiltration of polymorphonuclear eosinophils compatible with the diagnosis of eosinophilic ulcer of the tongue. The disease entity appears to be uncommon, yet, it should be recognized as benign since in both instances, healing was spontaneous.**

***(Arch Dermatol* 113:644-645, 1977)**

Eosinophilic ulcer of the tongue (EUT) is an entity that is seldom recognized and rarely considered in the differential diagnosis of ulcerated lesions of the oral mucosa. It is mentioned in only one textbook of dermatology.[1] The purpose of this article is to describe the occurrence of this entity in two patients and to emphasize that wide excision of this lesion is rarely necessary. The clinical history in one case supports the theory that trauma plays a major role in the etiology of this disease.

REPORT OF CASES

CASE 1.—A 53-year-old man was seen for a painless lesion of the tongue of five days' duration. Examination showed on the middorsal surface of the tongue, a round, punched-out ulcer measuring 1.2 cm in diameter with a gray-colored base (Fig 1). By palpation, there was no evidence of deep infiltration. The lingual mucosa surrounding the ulcer was faintly erythematous. The clinical diagnosis at the time of the biopsy was squamous cell carcinoma of the tongue.

Histologic examination of hematoxylin-eosin (H-E) stained sections of a biopsy specimen showed an area of ulceration and replacement of the surface epithelium by a homogenous pink staining fibrinous material containing numerous neutrophils and eosinophils. There were also numerous budding spores and mycelia suggestive of *Candida albicans*. At the base of the ulcer, there were an increased number of capillaries with prominent endothelial cells and surrounded by a cellular infiltrate consisting predominantly of eosinophils and also including numerous lymphocytes and histiocytes. The infiltrate extended through the submucosa and inbetween the striated muscle bundles (Fig 2 and 3).

The patient returned in five days. The entire lesion including the site of biopsy was completely reepithelialized. No recurrence or new lesions have developed within the past two years.

CASE 2.—A 14-month-old boy who had congenital indifference to pain was seen because of multiple recurrent areas of ulceration on the lips, tongue, and buccal mucosa. These developed soon after the eruption of his desiduous teeth and were presumably due to accidental biting of these areas. At the time of examination, there was an ulcer on the right border of the tongue measuring 3 × 5 mm in diameter and a second ulcer on the left border of the tongue measuring 5 × 7 mm in diameter. The borders of the ulcers were well defined, and the bases were bright red.

A punch biopsy specimen was taken from each lesion. The histologic sections showed areas of partial loss of the surface epithelium of the tongue. An extensive and predominantly eosinophilic, inflammatory cell infiltrate was present throughout the submucosa and extended into the layers of striated muscle. When the infant was prevented from biting oral structures, the ulcers cleared rapidly.

COMMENT

Eosinophilic ulcer of the tongue is considered a self-limited, benign disorder well differentiated from other eosinophil-containing lesions of the skin and mucosa, such as granuloma faciale and histiocytosis X, by the constant presence of ulceration and absence of definite granuloma formation. The etiology of eosinophilic ulcer of the tongue is not clear. Bhaskar and Lilly,[2] in 1964, studied traumatic lesions induced by crushing the tongue of rats with forceps and found the histologic changes very similar to those of EUT. In their preparations, even the pseudoinvasive quality of the infiltrate extending inbetween the muscle bundles was present. The clinical history of our second case supports the possibility of traumatic etiology for these lesions. In the first case, even though the lesion was covered by a thick layer of grayish membrane heavily invaded by spores and mycelia of *C albicans*, we do not believe that *Candida* played a primary role in the production of this lesion. There were no other manifestations of candidiasis such as thrush, paronychia, or intertrigo present in these patients. Also, it is not uncommon to see mycotic elements in the necrotic portion of ulcerated carcinomas in the mouth.

A review of 14 cases[3] disclosed that most lesions were treated by surgical excision and indeed, our case 1 resembled a carcinoma in its clinical appearance. The authors wish to call attention to this benign condition in the hope of preventing potentially mutilating and unnecessary surgical procedures.

This investigation was supported in part by Grant 9 R01 CA 13599 from the National Cancer Institute; the Zelda Radow Weintraub Cancer Fund, Inc; the Cancer Research Institute; and the Albert and Mary Lasker Foundation.

Foot Ulceration and Vertebral Osteomyelitis With *Corynebacterium haemolyticum*

Roger I. Ceilley, MD

• Diphtheroid or "coryneform" bacilli are usually considered to be nonpathogenic "normal flora" of human skin and mucous membranes. Because bacterial cultures are frequently contaminated with these organisms, the correct diagnosis and proper treatment may be delayed by the failure to recognize serious infections caused by them.

This is a report of a 71-year-old woman with a diabetic foot ulcer and *Corynebacterium haemolyticum* osteomyelitis with bacteremia.

(*Arch Dermatol* 113:646-647, 1977)

Cultures of wounds such as chronic leg ulcers growing diphtheroid organisms of *Corynebacterium* species are frequently reported as "normal flora" or "contaminants" by bacteriology laboratories. This group of organisms was thought to be a part of the harmless flora of human skin and mucous membranes and was implicated in lesser conditions such as acne,[1,2] erythrasma,[3] trichomycosis axillaris,[4] and pitted keratolysis.[5] However, there are a number of reports of more serious or fatal infections caused by them.

Goldberg[6] reported two cases of oral and facial infection with bacteremia caused from *Propionibacterium acnes* dental infection. Kaplan and Weinstein[7] reported nine cases of infection with diphtheroid organisms including endocarditis, wound infections, meningitis, osteomyelitis of the skull, and hepatitis. Other reports have included bacterial endocarditis,[8,9] meningitis and brain abscess,[10] osteomyelitis,[11] suppurative lymphadenitis,[12] pneumonia, and lung abscess.[13,14] Johnson and Kaye[15] reported 52 cases of serious infection caused by diphtheroid organisms; of these 60% of the patients had endocarditis and the remainder had a variety of infections including meningitis, osteomyelitis, and bacteremia. The most commonly identified organism in these reports has been *C pyogenes*, which is often associated with disease in farm animals. Infections in humans usually take the form of purulent lesions such as abscesses.[16]

Corynebacterium haemolyticum has been reported to cause acute respiratory illness, skin infection,[17] and brain abscess[10] but has not been implicated as a cause of osteomyelitis.

The following report concerns a diabetic woman with a foot ulcer and osteomyelitis who had pure cultures of *C haemolyticum* grown from specimens of her blood and first lumbar vertebra.

REPORT OF A CASE

A 71-year-old Pima Indian woman was admitted to the Phoenix Indian Medical Center with the complaint of "low back pain and foot ulceration." She had a 20-year history of diabetes mellitus that was controlled with diet and orally taken hypoglycemic agents. Complications of her diabetes included peripheral neuropathy with resultant foot ulcers, the most recent of which began three months prior to this admission. For the previous four to six weeks she had experienced increasingly severe back pain, especially in the upper lumbar region. She was bedridden for the three weeks prior to admission due to the severe pain.

Physical examination showed an elderly Indian woman who had complaints of back pain, and who had an oral temperature of 38.5 C. The chest was clear and there were no cardiac murmurs. There was kyphoscoliosis on the left side but no vertebral tenderness; however, there was significant paravertebral tenderness on the right side over the upper lumbar region. Straight-leg raising to 45° reproduced the patient's back pain. Her lower extremities demonstrated stasis changes. Her feet were severely deformed and several toes were absent, presumably due to neuropathy, trauma, and infection. There was a 2- × 3-cm ulcer with a clean base on the plantar surface of the right foot under the fourth and fifth metatarsal heads.

Pertinent laboratory data included the following: complete blood count with a hematocrit value of 28%, WBC count of 6,400/cu mm with a normal differential, and an erythrocyte sedimentation rate of 61 mm/hr. Urinalysis showed trace protein, and a urine culture grew less than 10,000 *Escherichia coli* per cubic centimeter. Serial measurements of fasting blood glucose were between 181 and 250 mg/100 ml. Serum protein electrophoresis revealed the following values: albumin, 2.65 mg/100 ml (normal, 3.5 to 4.7); α_1, 0.24 (normal, 0.23 to 0.39); α_2, 1.02 (normal, 0.59 to 0.91); β, 0.98 (normal, 0.69 to 1.37); γ, 4.09 (normal, 0.56 to 1.54); total protein, 9.00 (normal, 6.12 to 8.48); and albumin/globulin, 1:16. The remainder of the patient's laboratory tests, including urine for Bence-Jones protein, were normal or negative. Skin tests were negative for tuberculosis (both intermediate and second strength), coccidioidomycosis, and mumps.

A chest roentgenogram was normal. Roentgenograms of the feet disclosed considerable sclerosis of the metatarsals and proximal phalanges with multiple areas of bone fusion at the base of the metatarsals that were thought to be secondary to neuropathic changes. Roentgenograms of the lumbar spine demonstrated a destructive lesion of the anteroinferior aspect of the first lumbar vertebra, with definite disk-space narrowing of the pedicles (Figure). Vascular calcification and minimal changes of degenerative arthritis were also present.

Biopsy needle entering destructive lesion in first lumbar vertebra.

The patient was initially treated with bedrest and symptomatic care. Culture from the foot ulcer at the time of admission grew a diphtheroid organism. The culture was then discarded by the laboratory because it was thought to be a contaminant. On the fifth hospital day, a diphtheroid organism was isolated from the patient's initial blood cultures under both aerobic and anaerobic conditions. Subsequently, a closed needle biopsy of her first lumbar vertebra was done under fluoroscopic observation (Figure). Histologically there was acute and chronic inflammation and special stain preparations were negative for acid-fast bacilli. A culture of material taken at the biopsy grew a diphtheroid species. *Corynebacterium haemolyticum* was then identified from the blood and vertebral cultures by the Clinical Bacteriology Section of the Center for Disease Control, Atlanta. During the interim the patient was treated for possible tuberculous osteomyelitis with streptomycin sulfate, isoniazid, and ethambutol. She remained febrile on this regimen.

After identifying the *C haemolyticum*, which was moderately sensitive to penicillin and highly sensitive to ampicillin, the antituberculous drugs were discontinued and ampicillin was begun intraveneously, 2 gm every four hours. She soon became afebrile and had a gradual diminution of her pain. After six weeks of bedrest and intravenously administered antibiotic therapy, medication was changed to orally given ampicillin, 500 mg, and probenecid, 500 mg, four times a day. A Jewitt hyperextension brace was fitted and gradual ambulation was started after six weeks. The foot ulcer healed uneventfully. Observation four months later showed gradual healing of the vertebra and slow resolution of her pain.

COMMENT

Corynebacterium haemolyticum was first identified in 1946 by MacLean and co-workers when they isolated a hemolytic Corynebacterium that resembled *C ovis* and *C pyogenes* from infections of the nasopharynx and skin of American soldiers in the South Pacific.[17] This species differs from *C pyogenes* primarily by its lack of proteolytic activity and from *C ovis* in its fermentative characteristics and its failure to produce a filterable dermal or lethal toxin.[17,18]

Washington et al[10] reported the first case of brain abscess caused by *C haemolyticum* in 1970. Kaplan and Weinstein[7] noted that serious infections (most commonly bacterial endocarditis) caused by species of *Corynebacterium* other than *C diphtheria* usually occurred in patients with predisposing underlying diseases. Johnson and Kaye[15] listed valvular heart disease with or without valvular prosthesis, surgery or trauma, malignancies, anatomic abnormalities of the CNS, otitis media, postpartum meningitis, hyaline membrane disease, diabetes, gangrene, cirrhosis, and systemic corticosteroid and immunosuppressant drug treatment as predisposing factors.

The pathogenesis of this case is not entirely clear. The ulceration of her foot antedated the back pain and may have been the source of her osteomyelitis. The initial culture from the foot was reported as "diphtheroid" and was unfortunately discarded by the laboratory. Subsequent cultures from the foot were negative. The patient had no contact with animals other than a house dog but she frequently walked barefoot outdoors and on the dirt floor of her home.

The concept that diphtheroids are nonpathogenic for man has been discarded. It is likely that this case represents an example of an opportunistic infection that began in the foot ulcer of this diabetic lady. This is especially true in the vulnerable host such as the diabetic or immunosuppressed patient. A high index of suspicion will be needed by both the clinician and laboratory to make the correct early diagnosis of serious infections caused by these organisms.

Kenneth S. Eades, MD, Chief, Department of Radiology, Phoenix Indian Medical Center, Ariz, interpreted the roentgenograms.

Robert E. Weaver, MD, PhD, Chief, Special Bacteriology Unit, Center for Disease Control, Atlanta, identified the organism in this case.

Osler Node, Janeway Lesions, and Splinter Hemorrhages

Occurrence With an Infected Arterial Catheter

W. Lee Fanning, MD, Mark Aronson, MD

• This report documents the occurrence of an Osler node, subungual hemorrhages, and Janeway lesions peripheral to an infected arterial catheter. A brief review of these dermatological manifestations of infection is given and the importance of surgical removal of the involved artery after poor response to medical therapy is stressed.

***(Arch Dermatol* 113:648-649, 1977)**

Indwelling arterial catheters are utilized routinely to facilitate monitoring of blood pressure and blood gases in patients receiving intensive care for severe respiratory and cardiac disease. Complications described have included a 38% thrombosis rate,[1] a 23% peripheral embolization rate,[2] and a 4% infection rate.[3] Although common, these complications do not often cause serious difficulty. The following case report documents the unusual complication of an Osler node, Janeway lesions, and subungual splinter hemorrhages resulting from a staphylococcal infection of an indwelling arterial catheter.

REPORT OF A CASE

A 73-year-old woman was admitted to the Medical Center Hospital of Vermont for respiratory failure secondary to congestive heart disease. Because of the need for close monitoring of her blood gases, a right radial arterial catheter (18 gauge, 6 cm, catheter [Teflon]) was inserted percutaneously after 1% lidocaine anaesthesia and preparation of the skin with povidone-iodine (Betadine).

Four days after placement of the catheter, the patient complained of chills and developed a sudden temperature of 39.5 C. The WBC count was 12,000/cu mm with 78 neutrophils, nine nonsegmented neutrophils, 12 lymphocytes, and one eosinophil. Gentamicin sulfate, 100 mg every eight hours intramuscularly, was given after blood cultures were obtained from the arterial line and a peripheral vein. Twenty-four hours later purulent drainage was noted from around the arterial catheter. Gram stain revealed Gram-positive cocci in tetrads, the catheter was removed and cultured, the gentamicin stopped, and oxacillin 2 gm every four hours was begun. Coagulase positive *Staphylococcus aureus* sensitive to gentamicin and oxacillin grew from the catheter itself, blood obtained through the catheter, and blood from a peripheral vein.

Six days after catheter placement a tender erythematous nodule with a pale white center developed on the right ring finger (Osler node), subungual splinter hemorrhages were noted in the right hand, and multiple erythematous nontender papulo-nodular-hemorrhagic lesions (Janeway lesions) appeared on the dorsum of the hand, the palmar side of the fingers, and on the finger tips (Fig 1 to 3). No skin lesions developed at other sites and endocarditis was not clinically in evidence.

Despite continued oxacillin therapy, the patient remained febrile and developed a fluctuant erythematous area around the puncture site (Fig 4) that progressed despite antibiotic therapy. Surgical removal of the arterial segment was accomplished without difficulty under an axillary nerve block and a 5-cm segment of radial artery was removed that showed a false aneurysm. Microscopic examination of this segment revealed a large septic thrombus, severe suppurative arteritis, and periarteritis. Following surgery the patient recovered uneventfully receiving a total of two weeks of oxacillin and one week of di-cloxacillin. All lesions disappeared by two weeks after surgery.

COMMENT

Osler nodes, Janeway lesions, and subungual "splinter" hemorrhages are three of the major cutaneous manifestations of bacterial endocarditis. In the current antibiotic era they are infrequently seen in this disease,[4] but have been increasingly recognized as part of the clinical presentation of other illnesses.

Osler nodes were best described and given recognition as an important clue to endocarditis by William Osler[5] in 1909. In 1913 Weber[6] recognized Osler's contribution by calling the transient painful raised swollen areas with white centers seen in patients with bacterial endocarditis, Osler's sign. Pathologically, vascular inflammation has been found at the center of such lesions and bacteria have been demonstrated recently, suggesting an infectious pathogenesis.[7] Osler nodes have also been described in systemic lupus erythematosus, typhoid fever, gonococcemia, and hemolytic anemia.[8-10]

In commenting on the diagnosis of malignant endocarditis, Edward Janeway,[11] in 1899, described numerous small hemorrhages with a slight nodular involvement on the palms and soles and the arms and legs. Janeway lesions involving the fingers have also been described.[8] They appear in greater number than Osler nodes and unlike them, are nontender. In general, they are found with acute endocarditis, but are also found in subacute endocarditis.[8] Pathologically they show polymorphonuclear infiltration of capillaries with microabscess formation.[8]

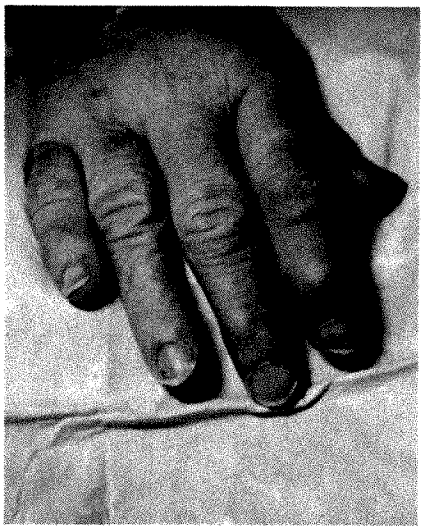

Fig 2.—Splinter hemorrhages are seen under fingernails of first and third fingers. Janeway lesions are noted on dorsum of hand and were nontender and slightly nodular.

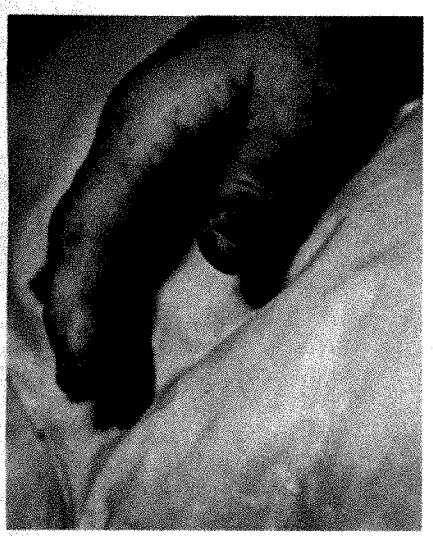

Fig 3.—Splinter hemorrhages are seen under thumb nail and a Janeway lesion is located on lateral aspect of index finger.

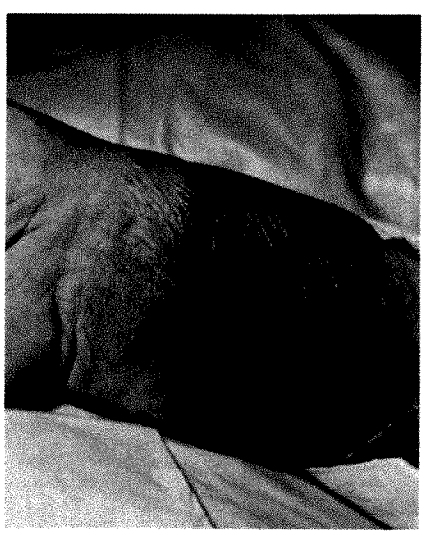

Fig 4.—Infected arterial catheter puncture site after removal of the catheter. Culture showed *Staphylococcus aureus*, coagulase positive.

1926 reported dark red streaks that resembled splinters underneath the fingernail in endocarditis. Although the specificity of this finding has been questioned since 18% of hospitalized patients have been reported to have splinters (primarily related to manual labor),[14] their development in a controlled setting without trauma and in the face of other signs of infection should make one suspect endocarditis. Other diseases in which they have been reported are trichinosis, vasculitis, and meningococcemia.[14]

The present case documents the development of an Osler node, Janeway lesions, and splinter hemorrhages in a patient with a staphylococcal infection of an indwelling arterial line. The pathogenesis of these skin lesions is unknown. Rarely have bacteria been cultured from these lesions and it is presently believed that they may be produced by an allergic mechanism,[1] although the rapidity of onset and their distribution in the current case argues in favor of an embolic etiology. The finding of an Osler node in a patient with an infected arterial catheter has been described once before with *Proteus mirabilis* being cultured from both blood and arterial catheter,[15] and splinter hemorrhages have been ascribed to noninfected arterial punctures.[16] Janeway lesions to our knowledge have not been previously described in this clinical setting.

Thus these three classical dermatologic signs may be produced from an infected indwelling arterial catheter and their presence dictates removal of the catheter for culture and initiation of antibiotics. Surgical removal of the infected artery may become as important as removal of an involved vein in septic thrombophlebitis.[17] Continued fever and clinical evidence of abscess formation around the vessel despite antibiotic therapy suggests the need for surgical intervention.

Modern Radiotherapy for Malignant Epitheliomas

A Measure of Last Resort

Anthony T. Farina, MD; Morris Leider, MD; Joseph Newall, MD; Richard J. Carella, MD

• **There are exceptional cases of malignant epitheliomas in which radiotherapy is at once or eventually becomes a treatment of last resort. We recount the clinical facts, histologic findings, radiotherapeutic techniques, and results of treatment of seven such cases.**

(*Arch Dermatol* 113:650-654, 1977)

Basal cell and squamous cell carcinomas are the most common malignancies of the skin, the former indeed the most common of all malignancies of any tissue. Relative to them, cutaneous sarcomas (eg, Kaposi, dermatofibrosarcomas, angiosarcomas, and lymphosarcomas) and malignant melanomas are uncommon, although generally much more serious. Nevertheless, basal cell carcinomas on rare occasions and squamous cell carcinomas more often can be or can become as life threatening as the worst of malignancies of any type, anywhere. Ordinarily, these cutaneous malignancies are clinically suspected early, are usually easily recognized grossly and correctly by the trained dermatologic eye, and are readily confirmed by biopsies that are simple to perform. Ordinarily again, the average case is quickly and completely curable by any of several simple procedures that do not require highly complicated techniques or elaborate instruments. Curettage and electrodesiccation and minor, conventional scalpel surgery are the methods most commonly and satisfactorily employed because they are suitable for the usual case and practicable by most physicians. Radiotherapy could be used as often and as well for the general run of cases, but is used less often because it requires special skill and expensive, complex equipment. Cryotherapy with liquid nitrogen is a novel method that is reasonably effective for many cases, especially those that are multiple and superficial; chemosurgery is highly effective for any type of malignant epithelioma but is best reserved for the worst ones because of its requirement of several successive operations with a special technique and immediate, repeated histologic examinations of the surgical specimens—all by a team of specially trained personnel.

Recurrent and long-neglected malignant epitheliomas, those with instantly, inherently, and unusually aggressive biologic behavior (the multicentric, the "field fire," the burrowing varieties), those that are ill defined, and finally, those occurring around the eyes and in the nasal grooves are much more serious and difficult to manage than are average cases on the general expanse of the skin. The best and most definitive method for most such cases is, no doubt, chemosurgery, according to the original method of Mohs or recent refinements upon it (so-called fresh-tissue technique). There are, however, some such cases in which chemosurgery or major conventional surgery are contraindicated ab initio because the lesions have become too large from neglect, misdiagnosis, or rapid development or because they are situated in such a way in and about parts like the eyes,

nose, ears, or deeper structures that must not be disturbed; or because poor general health, extreme debility, or advanced age does not permit surgery of any sort. And finally, there are occasional cases in which chemosurgery and conventional surgery of the most formidable sort fail to eradicate elusive malignant epitheliomas. In instances of these kinds radiotherapy becomes a modality of last resort that often ends in cure at best or control of progression for gratifyingly long times at least.

Following are seven representative cases in which radiotherapy was practiced in desperation when no other treatment was feasible or after all other reasonable forms of treatment had been accorded and failed. They illustrate what can be accomplished by modern radiotherapy under such circumstances.

REPORT OF CASES

Case 1.—About 20 years ago, a man now 74 years old had a squamous cell carcinoma resected from the upper lip followed by radiotherapy of unknown quality and quantity. Thirteen years later, in 1968, he developed several seemingly disparate lesions on the face about the nose. These lesions were treated indifferently until about a year later when he began to suffer continuous bloody discharge from the nose. By this time he was found to have an extensive, ill-defined mass involving the columella, septum, and walls of the nose (Fig 1). The tumor extended onto the upper lip. There were also two separate lesions, one in the right nasolabial groove and the other on the skin overlying the angle of the right mandible. Several biopsy specimens were taken and all were read as basal cell carcinoma. The process in and about the nose was deemed too extensive for chemosurgery or conventional surgery. Instead, it was irradiated with an apparatus that operated at 280 kV and 20 mamp, at a skin-target distance of 50 cm. The half-value layer was 3.1 mm of copper (Cu). From Oct 20 to Nov 7, 1969, a total dose of 5,000 rads was administered through a 6- × 8-cm portal in 15 fractions. The lesions in the right nasolabial groove and on the skin overlying the angle of the right mandible were simultaneously irradiated with an apparatus operating at 120 kV and 8 mamp, with added filtration of 3 mm of aluminum and a skin-target distance of 20 cm. The half-value layer was 3 mm aluminum. From Oct 20 to Oct 31, 1969, the lesions received a total dose of 4,500 rads each in ten fractions. The patient was seen at regular intervals until July 1973 (follow-up of 3½ years), at which time there was still no evidence of residual or recurrent disease (Fig 2).

Case 2.—A 58-year-old man became aware of a lesion on the pinna of the right ear seven years ago (1968). It was treated nonspecifically for two years and eventually was resolved by biopsy findings to be a basal cell carcinoma. By that time the lesion was extensive and involved the entire periauricular area. In November 1970 extirpation of the neoplasm was attempted by the chemosurgical technique. Four months later, in April 1971, recurrence of the malignancy was found and extirpation was again attempted by chemosurgery. Four months after that, in August 1971, the patient developed a deep ulceration at the angle of the mandible and a nodule behind his right ear (Fig 3). Results of a biopsy confirmed the clinical suspicion of more basal cell carcinoma. Tomograms of the right auditory canal and a routine skull series were normal. The malignancy was now considered too extensive to resect and the patient was referred for radiation therapy. The involved area was treated from Sept 9 to Oct 14, 1971, with a 280-kV apparatus (see other factors in case 1) and received a total dose of 6,000 rads in 25 fractions through a 6.5- × 6.5-cm portal. The mass responded well and seemed to disappear, although the area never epithelialized again completely. The local site remained reasonably well for about a year, at which time clinical evidence of cutaneous recurrence appeared and was proved by biopsy findings (Fig 4). It was the opinion of consultant surgeons that no definitively curative surgical procedure was possible because the malignancy was then found by use of roentgenography to involve the base of the skull. In October 1972 the accessible cutaneous component alone of the recurrent process was excised under local anesthesia. The patient survived comfortably for one year; he died at age 65 years of cardiovascular disease and not of the malignancy.

Case 3.—Six years ago, a 76-year-old man began to develop an elevated lesion on the left cheek. It was observed for an unduly long time and was eventually (in January 1972) resolved at biopsy to be a basal cell carcinoma. By then the lesion was extensive and involved nearly the entire left side of the face (cheek, upper and lower eyelids, upper lip, and nose) (Fig 5). The lower eyelid and ala nasi were nearly completely destroyed by the malignant process. The patient had bilateral cataracts and no useful vision in the left eye. Because the size and location of the malignancy and the patient's poor cardiovascular condition precluded surgery, radiotherapy was resorted to. The involved area was irradiated with an apparatus operated at 280 kV and 20 mamp, at a skin-target distance of 50 cm; the half-value layer was 3.1 mm Cu. Treatment was given over a period of a month (from Jan 17 to Feb 15, 1972). He received a total dose of 5,500 rads through a 8- × 9-cm portal in 20 fractions. During the course of radiation therapy the malignancy was seen to regress gradually, and within six weeks from the start of treatment, seemed to have vanished. The skin was completely epithelialized again in another six weeks. The patient has been followed up at regular intervals and at last examination in September 1975 (follow-up of 3½ years) there was no clinical evidence of disease (Fig 6).

Case 4.—A 39-year-old man, a native of Italy, developed a lesion on the bridge of the nose in 1960. A biopsy was done and the lesion was confirmed to be basal cell carcinoma; it was treated with a radium mold (technical details not available). In June 1967 the epithelioma recurred and was managed by local excision and skin graft. In the following four years several more recurrences appeared and were also treated by conventional scalpel surgery. All of the above treatments were accorded in his native land. By March 1971 the malignancy was extensively recurrent, involved the entire glabella, and extended onto both the right and left medial canthi. The patient was brought to the United States specifically for chemosurgery. Extirpation was attempted by the chemosurgical technique, but the procedure had to be abandoned when the underlying bone was found to be invaded by the malignant process. In April 1971 radical excision of the nasal bones, outer table of the frontal sinus, anterior ethmoid cells, and nasal process of the frontal bone were done here. The histologic sections showed basal cell carcinoma in fragments of bone and in all specimens of the exposed respiratory epithelium. One year later (May 1972) extensive, recurrent basal cell carcinoma developed in the middle third of the left side of the face with invasion and destruction of the left globe. There was also suspicion of malignant process on the medial wall of the right orbit. Exenteration of the left orbit was done and biopsy specimens were taken of the right posterior ethmoid cells, medial wall of the right orbit, and conjunctiva of the right eye. All of these sites were histologically positive for malignancy (Fig 7). The patient was referred for radiotherapy, and from June 22 to Aug 8, 1972, the entire area judged to be affected by the malignancy was irradiated with a telecobalt

apparatus. A total dose of 6,500 rads in 28 fractions over a period of 47 days was administered through a 9- × 9-cm portal. A bolus in the form of gauze was placed over the area to be irradiated throughout the course of treatment to bring the maximum action of the cobalt 60 gamma rays to bear upon the most superficial part of the malignant process.

The patient returned to Italy. At last follow-up by correspondence in December 1974 (2½ years after radiotherapy) he was alive, well, and had vision in the remaining right eye, although otherwise he was sadly mutilated.

CASE 5.—A 61-year-old woman developed a "swelling" in the region of the left nasolabial fold in 1968. The lesion persisted, and it was not until 1972 that a biopsy was performed. At the time the lesion was reported to be a benign keratoma. In May 1973 the patient developed pain in the general area of the lesion. When that symptom persisted, another biopsy specimen was taken in September 1973; this time it was reported to be a trichoepithelioma. Dissatisfaction with the behavior of the process impelled a third biopsy in November 1973, and then the presence of morphea-type basal cell carcinoma was disclosed. By then the tumor was extensive and involved a large portion of the left cheek, the left lower eyelid, the left side of the nose, the left nasolabial groove and fold, and the left upper lip (Fig 8). The lower portion of the tumor on the upper lip extended beyond the midline to the right side. Roentgenographic examination of the facial bones was normal. In consultation, the consensus was that surgery would require so massive a resection that an unacceptable cosmetic result would ensue in this patient who, moreover, rejected the very idea of any surgery. Radiotherapy became the sole resort. The malignancy

was irradiated with an apparatus operated at 280 kV and 20 mamp, at a skin-target distance of 50 cm; the half-value layer was 3.1 mm Cu. Treatment was given from Dec 5, 1973, to Jan 7, 1974. A total dose of 5,000 rads in 20 fractions through a 10- × 10-cm portal was received. During the course of treatment there was gradual regression of the tumid process, which upon completion of the full course was about half its original bulk. During the year following completion of the radiation therapy, the mass continued to regress slowly and in December 1974 was about a quarter of its original size (Fig 9). In the follow-up period to date (15 months), further regression has occurred, and there is as yet no compelling reason to warrant another biopsy.

Case 6.—An 81-year-old man began to develop a palpable mass behind the lobe of the right ear about three years ago. The lesion gradually enlarged and one year later involved the entire surface of the right earlobe and extended onto the posterior auricular groove. Results of a biopsy proved it to be basosquamous carcinoma. The malignancy was treated by electrodesiccation and curettage. One year after that, in November 1973, it was clinically evident that there was persistent disease on the lobe of the right ear, and extirpation was again attempted by electrodesiccation and curettage; however, it had to be abandoned when it became apparent that the process was too extensive to be eradicable by that method. A month later, in January 1974, the malignant process was found to extend from the now partially mutilated right earlobe onto the skin overlying the inferior temporal region and the parotid gland (Fig 10). It was the opinion of several surgeons that there was too high a risk of damaging the facial nerve if this lesion were to be excised by conventional scalpel surgery. It was therefore irradiated with an apparatus operated at 280 kV and 20 mamp, at a skin-target distance of 50 cm and a half-value layer of 3.1 mm Cu. Treatment was given from Jan 28 to Feb 14, 1974, to a total dose of 5,000 rads in 15 fractions through a 4 × 7-cm portal. Upon completion of the radiotherapy, the massive process had completely disappeared. To date, a regular follow-up for more than one year has disclosed no evidence of local disease.

Case 7.—A 74-year-old woman became aware of a skin change on the right side of the forehead four years ago. It was observed and treated conservatively for a time, but when it persisted unduly was finally resolved by biopsy to be a morphea-type basal cell carcinoma. By this time it was extensive and involved much of the skin on the right side of the forehead and scalp; numerous papules, crusts, and an ulcer measuring 1.5 cm in diameter were present in the area of involvement. Immediately prior to treatment, in July 1973, a biopsy specimen of the lesion was taken again, and basal cell carcinoma was reconfirmed. The lesion was excised by the fresh-tissue technique of Mohs, and all the margins were judged to be clear of malignancy. Three months later, however, in September 1973, there was clinical suspicion and then histologic proof of recurrence involving the frontal area of the scalp and brow, the eye, the ethmoid sinuses, and the zygomatic region, all on the right side. There was also exophthalmus of the right eye from extensive orbital involvement. The patient was then subjected to radical excision of the skin and subjacent tissue of the frontal area, orbital exenteration, and ethmoidectomy. Six months later, in March

1974, a lesion appeared on the left side of the forehead, which upon biopsy proved yet again to be a basal cell carcinoma. Extirpation was again attempted by the fresh-tissue technique of Mohs and this time had to be abandoned when it was found that the malignancy was too extensive and deep to be resectable by this method. It had extended from the supraorbital ridge deep into the left frontal bone (Fig 11). Tomograms of the left orbital bones were fortunately normal. In an attempt to save the remaining eye, which would have had to be sacrificed if surgery were practiced, the patient was referred for radiation therapy. The malignant process was irradiated with an apparatus operated at 280 kV and 20 mamp, at a skin-target distance of 50 cm and a half-value layer of 3.1 mm Cu. From March 18 to April 12, 1974, a total dose of 5,000 rads in 20 fractions was delivered to the area through a 6.6- × 8.0-cm portal. The eye was protected by lead shields. By the time the course of radiotherapy was completed, the extensive process had disappeared. As of the last follow-up in December 1974 (eight months later), no evidence of local disease could be detected, and the remaining eye was functional.

COMMENT

Electromagnetic energy of any wavelength and in any amount (particularly that of the spectrum from ultraviolet to gamma radiation) is harmful to animal tissues when directly applied. After plant life, living things have no means or need of utilizing electromagnetic energy directly applied, except in conversion of ergosterol to vitamin D early in life. Depending upon wavelength, duration of irradiation, and kind of tissue, the degree of harm from electromagnetic energy may be trivial, temporary, transient, and remediable or instantly severe and progressively and irremediably destructive. With modern knowledge of the relative radiosensitivities of normal and abnormal tissues and with versatile modern equipment, this fact of harmfulness of electromagnetic energy can be turned to good by selective focusing of it upon radiosensitive abnormal tissue. This is the fortunate situation in many instances of cancer in which cancerous tissue is more radiosensitive than normal tissue, in which it is not affordable to sacrifice much normal tissue surgically, or where normal tissue has to be preserved absolutely for functional and cosmetic reasons. Such were the circumstances in the cases recounted here.

It has become possible now, and may become even more so in the future, to apply electromagnetic energy so artfully that many more instances of seemingly hopeless cancers of the skin and elsewhere may be cured outright or significantly alleviated by this relatively clean and painless means. Given that the extent, depth, and dispersion of malignant process is determinable by clinical judgment and by other more precise means like standard and special radiography, given proper equipment (x-ray machines of grenz, superficial, orthovoltages and megavoltages, radioactive cobalt, and other sophisticated generators of electromagnetic and particle energy), and finally, given proved experience of effective and bearable dosage, skillful application of destructive energy can eliminate abnormal tissue that mechanical means (like the curette, knife, cautery, and refrigeration), cytotoxic drugs, and immunologic strategems may not as yet be able to do.

This is not the place to go into fine details about radiotherapeutic technique as practiced by nondermatologic specialists in radiotherapy beyond saying that field size, total dose, fractionation, shielding, penetrability, and depth of effective dose, choice of machine, and known radiosensitivity of normal and abnormal tissues are some of the factors that enter into the plan and design of treatment in particular cases. Such was the practice in the cases reported, and if the results were not in every instance curative, some good in the form of halting progression of malignancy and no worsening were always achieved.

Panniculitis of the Legs With Urate Crystal Deposition

Report of a Case

Kirsti-Maria Niemi, MD

• Dark red nodules that drained an opaque amber liquid developed on the extensor surfaces of both legs in a 69-year-old woman receiving furosemide and spironolactone for congestive heart failure. In addition to asymptomatic cholelithiasis, the serum amylase, lipase, and uric acid levels were elevated. Other skin signs and joint manifestations of gout were absent. A biopsy revealed a granuloma with the needle-like crystals characteristic of gout.

(*Arch Dermatol* 113:655-656, 1977)

In this report a patient is described who had subcutaneous fat necrosis on the legs as the only cutaneous sign of gout.

REPORT OF A CASE

This 69-year-old woman was admitted to the hospital because of tender suppurating nodules on the anterior aspects of her legs of six months' duration in August 1975. The nodules were large, thick, and dark and drained an opaque fluid (Fig 1). Both legs were edematous. For two years she was given spironolactone and furosemide regularly for cardiac failure. There had been varices of both legs for at least ten years and a superficial thrombophlebitis occurred in the right leg six years ago. She had a history of severe arthrosis of both hip joints for several years. Arthroplastic surgery with endoprothesis was performed on the left hip joint in 1972. Arthrosis was also manifest in the finger and knee joints.

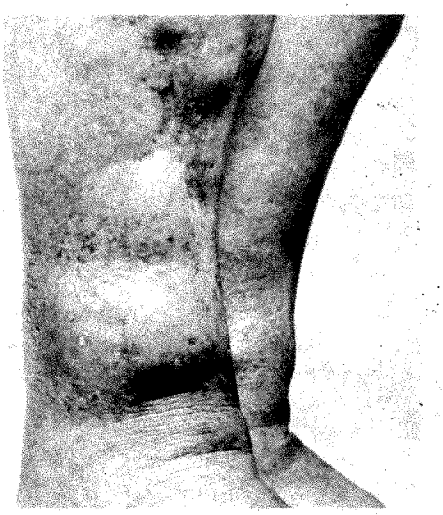

Fig. 1.—Large nodules around edematous legs. Nodules discharged opaque fluid from small fistules or real ulcers.

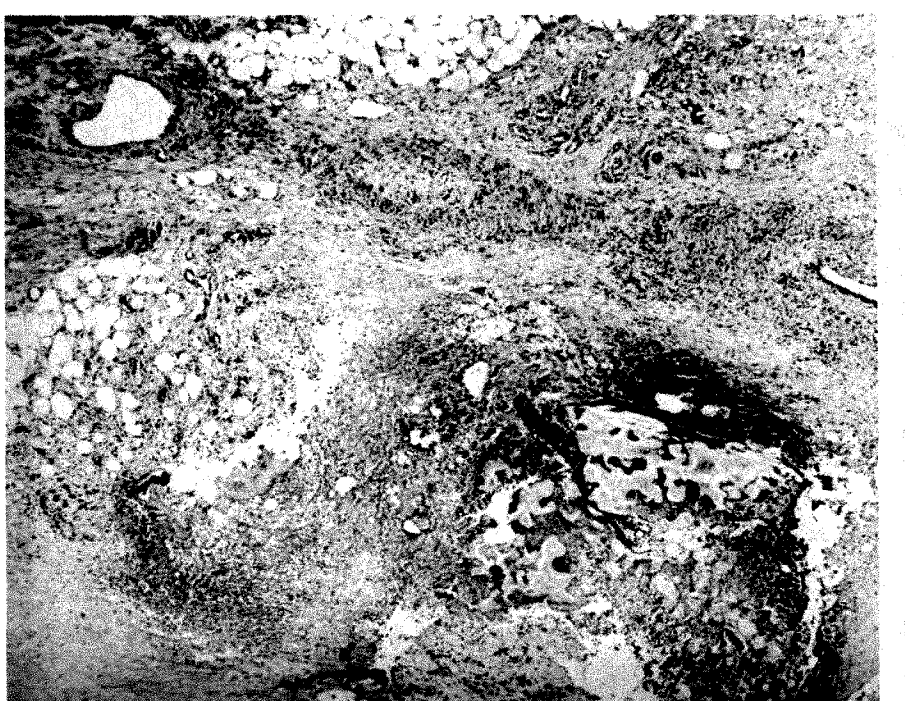

Fig 2.—Subcutaneous fat necrosis with palisade arrangement of fibroblasts (hematoxylin-eosin, 2.5 × 12.5).

Accepted for publication March 17, 1976.

From the Department of Dermatology, University Central Hospital, Helsinki.

Reprint requests to the Department of Dermatology, University Central Hospital, SF-00170 Helsinki 17, Finland (Dr Niemi).

Fig 3.—Blue-staining homogenous bodies within necrotic area (hematoxylin-eosin, 10 × 12.5).

Fig 4.—Doubly refractile needle-like structures consistent with urate deposits on polaroscopic examination (hematoxylin-eosin, 40 × 12.5).

Asymptomatic cholelithiasis was found during her hospitalization.

A skin biopsy (Fig 2) showed extensive subcutaneous fat necrosis. Palissading fibroblasts and histiocytes surrounded the necrotic area. Within this palissading granuloma were large, homogenous, discrete areas that stained pale blue (Fig 3). In one corner there were large needle-like crystals that were birefringent in polarized light (Fig 4). The amorphous areas and crystals were consistent with urate deposits.

Her serum uric acid concentration was 9.9 mg/100 ml, ie, twice the normal value. Also serum amylase concentration was 438 units/liter with normal 70 to 300 units/liter amylase test (Phadebas)[1] and serum lipase concentration of 1.95 Tietz-Units was elevated. Serum creatinine level was 1.3 mg/100 ml and creatinine clearance was 40 ml/min which is below normal. Serum glucose concentration was 105 mg/dl and in the oral glucose tolerance test the two-hour value remained at the level 205 mg/dl. Sedimentation rate was 92 mm/hr. Findings from hemoglobin level, hematocrit reading, WBC and differential cell counts, serum sodium, potassium, calcium, phosphate, total bilirubin, and protein concentrations were normal. Serum protein fractions in cellulose acetate electrophoresis were normal although serum albumin concentration 32 gm/liter was slightly below normal. Serum aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase[2] as well as serum thyroxine were normal. A low protein, purine diet was ordered and allopurinol, 300 mg, and probenicid, 500 mg, were administered. Spironolactone (50 mg), furosemide, 80 mg daily, and digoxin were also continued. Within six weeks the lipase and uric acid levels returned to normal.

COMMENT

According to Lichtenstein et al,[3] extraskeletal deposits of urates in the skin and subcutis of gouty subjects are usually found on the ears, hands, and feet. Gottron and Korting[4] described skin deposits only on the hands adjacent to joints. In our patient tophi were not found on these usual locations. She had never had acute gouty arthritis, and had no family history of gout. This does not, however, exclude primary gout.[5] This patient had neither hemopoietic disorders nor other diseases that are known to cause an elevation of serum uric acid. Treatment with spironolactone and furosemide, well-known blocking agents of the renal secretion of uric acid, could explain the elevation in serum uric acid.[6] Antecedent fat damage caused by elevated serum amylase and lipase levels as well as circulatory stasis in the legs secondary to varices and cardiac failure, probably contributed to the deposition of urate in the skin. Pancreatic disease is known to cause suppurative panniculitis of the legs.[7,8] Secondary gout should be added to the growing list of disorders associated with nodose lesions of the lower extremities. The use of diuretics has increased the occurrence of secondary gout, and this could in turn lead to other unusual cutaneous manifestations.

Skin Changes in Short-Bowel Syndrome

Kwashiorkor-like Syndrome

Stephen Z. Smith, MD

• An infant with short-bowel syndrome developed flexural desquamation and "enamel paint" skin in pressure-bearing areas. Hyperalimentation with amino acid and lipid solution was unsuccessful in correcting the malnutrition and skin changes.

(*Arch Dermatol* 113:657-659, 1977)

In severe malnutrition in infancy from the short-bowel syndrome, parenterally given nutrition must supply electrolyte, amino acid, vitamin, mineral, and fatty acid. The importance of adequate fatty acid supplementation has been demonstrated in animals,[1] infants,[2,3] and adults.[4,5] Dry, scaly, erythematous lesions of the neck, axilla, antecubital fossa, and groin and generalized xerosis are seen. The patient whose case we report had skin changes similar to those reported in other cases, but the changes fit the description of the cutaneous signs of kwashiorkor.[6,7]

REPORT OF A CASE

A 6-week-old male infant was the product of a normal term pregnancy and delivery. Vomiting occurred with formula-feeding, but abated with an alternate formula. He gained only 255 gm from his birth weight of 3,164 gm during the first month. He was admitted to another hospital with a four-day history of fever, vomiting, and diarrhea and was severely emaciated, dehydrated, and distended. Bowel sounds were diminished; x-ray films showed large- and small-bowel distension. Initial impression was a severe gastroenteritis with ileus. Exploratory laparotomy on Nov 26, 1975 disclosed multiple large segments of necrotic small bowel (lower jejunum and ileum), which were resected, and multiple liver abscesses. Pathological diagnosis was "necrotic bowel" of undetermined origin. Systemic administration of antibiotics was begun, and the patient was transferred to the University of California at San Francisco for hyperalimentation.

The infant was treated with fluids to compensate for severe third-space losses secondary to his disease, and surgical correction was carried out. He was placed on a regimen of gentamicin sulfate and ampicillin sodium because of apparent Gram-negative septicemia and shock. His hospital course was characterized by thrombocytopenia (platelet count, 50,000 to 60,000/cu mm), leukocytosis (WBC count, 30,000/cu mm with 89% polymorphonuclear leukocytes, 7% lymphocytes, 3% monocytes, and 1% eosinophils), and a decreasing hemoglobin level (14 to 8 gm/100 ml). Elevated prothrombin time and partial thromboplastin time were treated with phytonadione and fresh frozen plasma. Total serum protein, serum albumin, and serum globulin levels were 2.1, 1.1, and 0.9 gm/100 ml, respectively (all below normal), but immunoelectrophoresis results were normal. Phenobarbital was required to control grand mal seizures, which began on Nov 28. On Dec 3, an x-ray film disclosed a pneumoperitoneum; subsequently, exploratory laparotomy demonstrated several punctate bowel perforations. After this procedure, hyperalimentation was begun with 3% amino acid synthetic solution (Freamine) and 5% glucose in water.

There were no skin changes on admission, but on Dec 4, he was noted to have flexural erythema and scaling. Results of examination revealed antecubital and popliteal fossae with brownish-red, well-defined, waxy, scaled lesions that fissured along tension lines (Fig 1, left and right) and that easily desquamated large flakes of scale. His neck had similar, though less dramatic changes. The cheeks, buttocks, and localized areas of the back showed brown, scaling patches where contact with the incubator had been made. The groin and incisional regions had superficial ulcerations (Fig 2). Skin cultures grew a few colonies of *Staphylococcus epidermidis* and *Proteus mirabilis*. Completely normal-appearing skin on the extremities and trunk, aside from the areas described above, remained clear throughout the hospital course.

The scalp was normal, except for a 2-cm oval region of hair loss that resulted from protracted pressure. The clinical similarity of this patient's cutaneous eruption and the history of malabsorption suggested a protein and/or fatty acid deficiency. Initially, sunflower acetyl oil[8] was applied to the skin of the forearm; there was no improvement after three days. Intravenous administration of soybean oil (Intra-

Accepted for publication June 10, 1976.

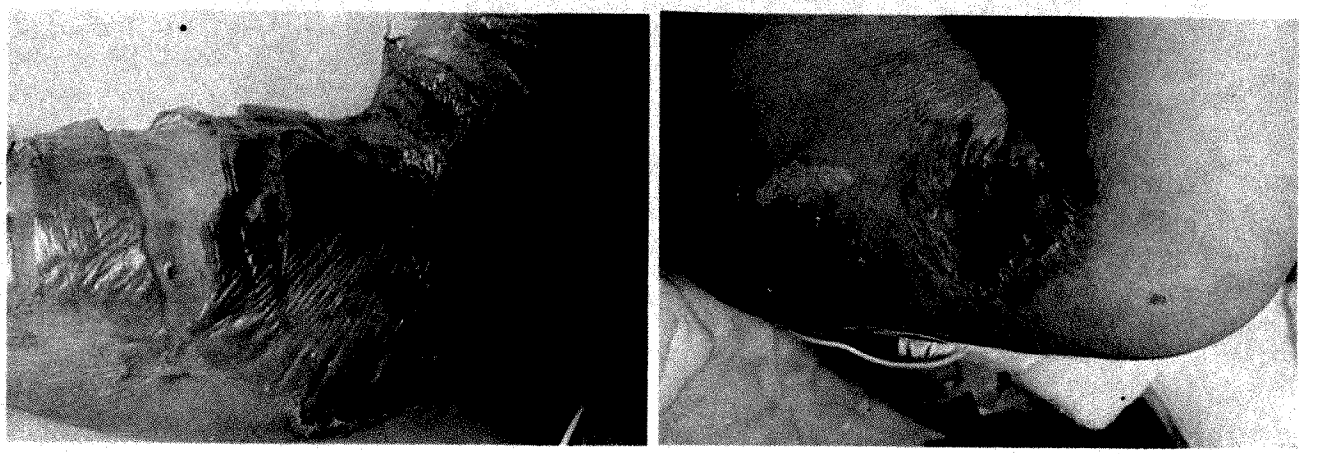

Fig 1.—Right antecubital fossa and right popliteal fossa showing waxy, scaled lesions fissuring along tension lines.

Fig 2.—Superficial erosions in groin and incisional region.

lipid [Sweden]; no comparable US product) in a 10% solution was begun. Progressive deterioration with recurrent bowel perforation, *Pseudomonas* sepsis, hematological chaos, and respiratory collapse led to death on Dec 9. No change in the skin lesions occurred during the last days of life.

Family history disclosed that one male sibling had died shortly after birth with gastroschisis.

Autopsy findings revealed malignant histiocytosis involving the small bowel, bone marrow, esophagus, liver, and spleen. Sections of involved and uninvolved skin showed no abnormal histiocytes. Neither lymph nodes nor thymus were abnormal. Involved skin showed minimal hyperkeratosis and acanthosis, with normal corium and subcutaneous tissue.

COMMENT

Kwashiorkor in its polar form results from a diet that is poor in protein, qualitatively and quantitatively, but that supplies adequate to excessive caloric intake, usually in the form of sugar or starch. Marasmus, on the other hand, is a condition that results from total caloric deprivation, including protein, sugar, starch, and other nutrients. The skin in the marasmic child is loose, wrinkled, and dry, but lacks the edema and dermatosis that delineate kwashiorkor.[6,7] Most reports of kwashiorkor are from the Middle East and Africa, where nutrition is usually adequate in calories but bereft of proteins. The stunted child with bulbous abdomen, moon facies, edematous skin, and psychomotor abnormalities is the frightful result. Trowell[9] gave the classical description of kwashiorkor's cutaneous findings. The "enamel paint" skin he described starts with erythema, but rapidly is followed by purple patches that feel waxy and are sharply demarcated from the adjacent normal skin. Since these changes occur in pressure areas (knees, elbows, buttocks) and flexures (groin, popliteal, and antecubital fossae), movement initiates cracking of the skin. Its "flaky paint" character, as described by Trowell et al,[10] can be seen in Fig 1 and 2, and in the photographs of McLaren and Gillman.[6,7] Less often, several lesions coalesce to form large reddish-brown flaking patches that are hard, dry, and fissured. Large areas of skin may be eroded.[6-9] Linear fissuring of the flexures (Fig 2) beneath the toes, foreskin, and oral commissures disclose raw, tender skin, which limits movement. Any shearing or pressure force is met with little resistance, and blister formation is common. Depigmentation, pallor, characteristic hair changes, and nail deterioration are hallmarks of advanced disease.[11]

The remarkable similarity of this infant's cutaneous changes to those described above and the remark of McLaren[6] that extensive intestinal

resection has resulted in similar cutaneous changes were the bases for the diagnosis of iatrogenic kwashiorkor. The loss of a substantial portion of the intestinal tract made nutrition impossible without total parenteral supplementation. The infant had been sustained seven to ten days with inadequate, but life-supporting nutritional intravenous mixtures, mainly carbohydrate in caloric content. The flexural erythema began shortly before parenteral hyperalimentation. The postmortem diagnosis of histiocytosis X was unsuspected. Cutaneous changes in histiocytosis X[12-14] classically show purpuric, greasy, scaly papules that occur in crops on the scalp, face, neck, trunk, and buttocks. Crusting lesions rarely occur in flexures, but have a papular component. There are no reports of the marked sheet-like desquamation that occurred in this case. Fatal familial histiocytosis (Barth et al[15]), a malignant histiocytic disease with invasion of the reticuloendothelial system, has eosinophilia, primary immunodeficiency, profound lymphocytic depletion of lymph nodes, thymus, spleen, and gut lamina propia, and a generalized maculopapular skin rash; these findings were not present in this case.

The reports of Riella et al,[5] Paulsrud et al,[2] and Caldwell et al[3] brought attention to the possible role of fatty acid metabolism in the pathogenesis of these skin changes. Aaes-Jorgensen[16] extensively described the scaly erythematous skin; none of these reports demonstrated the marked severity or extent of lesions as in our case. The impelling need to reverse the rapid, downhill clinical course precipitated the use of sunflower seed oil shown by Press et al[8] to be effective in replacing essential fatty acids, particularly linoleic acid. Simple regular application to flexor aspect of the forearms resulted in sufficient percutaneous absorption of lineoleic acid to reverse fatty acid deficiency syndrome in several weeks. Recent studies[16-18] reported a characteristic abnormal lipid pattern in fatty acid deficiency that reflected the requirement for lineoleic acid, a nonbiosynthesized fatty acid. However, administration of neither sunflower seed oil nor soybean oil in 10% solution reversed the clinical course. Riella et al[5] corrected fatty acid deficiency and reversed the cutaneous changes with soybean oil, but two weeks of therapy were required.

This case illustrates the cutaneous signs of malnutrition in infants with major bowel resection. Early recognition may permit institution of total parenteral alimentation with protein and fatty acid precursors. The necrotic bowel that required resection in this child resulted from terminal histiocytosis, but in other cases of short-bowel syndrome, adequate parenteral alimentation is very important. Perhaps the restitution of nutritional needs would make the seriously ill infant more capable of withstanding the attack of infections, electrolyte shifts, and hematologic abnormalities. Adults have similar cutaneous changes[5,19] that presage nutritional insufficiency; early recognition should be useful in managing patients receiving total parenteral alimentation.

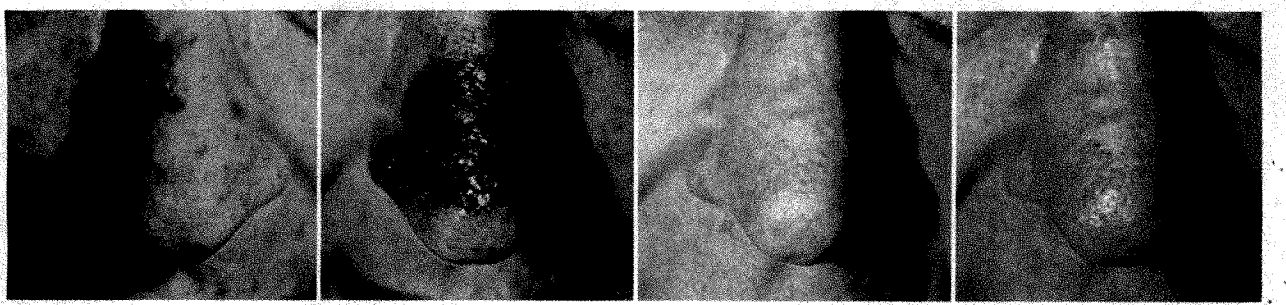
Roche Laboratories announces an additional therapeutic application for Efudex® 5% Cream fluorouracil/Roche

now indicated for superficial basal cell carcinoma



8/8/69
Before treatment a superficial, scaly, slightly excoriated lesion was present. Biopsy revealed the lesion to be a superficial basal cell carcinoma.

9/25/69
After 7 weeks of treatment with Efudex (fluorouracil) 5% Cream, lesion site is clearly delineated, markedly erythematous; surrounding skin shows no reaction to medication. Treatment terminated.

12/10/70
Follow-up approximately 14 months after treatment; healing has occurred with minimal scarring.

4/18/74
Patient has been followed continuously since treatment. **No evidence of recurrence.**

Efudex (fluorouracil) 5% Cream is recommended as an effective topical alternative to surgery for multiple lesions and difficult treatment sites.

A proven cytotoxic agent that exerts a marked effect on cells that grow more rapidly.

Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity. Normal tissue rarely affected. Convenient, economical b.i.d. application.

Prolonged exposure to ultraviolet light may accelerate reaction to medication. If an occlusive dressing is used, there may be an increase in the incidence of inflammatory reactions in the adjacent normal skin.

An exclusive Roche formulation

Efudex® 5% Cream
fluorouracil/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).
Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.
Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.
Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.
Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity **(only 5% strength recommended)** to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.
How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

So Why Shouldn't Abrasive Cleansers?

All patients' skins differ in some respects. Some acne patients are fair-skinned; others have "tough" skin. Some can tolerate only fine abrasive cleansers; others need more strenuous abrasion to provide proper desquamation.

Brāsivol—Fine, Medium and Rough—provides this range of abrasiveness and even is supplied without abrasive—as Brāsivol Base—for exquisitely sensitive skin.

Brāsivol Base, Fine, Medium and Rough are available in unbreakable jars.

Write for professional samples today.

Review Article

Newer Concepts of Atopic Dermatitis

Jon M. Hanifin, MD, Walter C. Lobitz, Jr, MD

Atopic dermatitis is a disease of fascination and frustration to medical practitioners and researchers. This very common disorder is confusing from several standpoints. The confusion begins with nomenclature; in discussions with American nondermatologic physicians, we might hear atopic dermatitis referred to as "eczema," allergic dermatitis, allergic eczema, or even neurodermatitis. Many Europeans continue to use the term prurigo Besnier.

Diagnostic features of atopic dermatitis are another source of confusion. The skin lesions a pediatrician sees on a child's skin may be vastly different from the lesions the general practitioner sees on that same individual 15 years later. There may be no single distinguishing characteristic; diagnosis may depend on a combination of morphologic, distributional, and historical features. Histological findings provide very little aid in diagnosis, though a recent preliminary report by Mihm et al[1] raises the hope that new histologic techniques may reveal distinct histopathologic features in atopic dermatitis.

With such loose nomenclatural and diagnostic guidelines, many past studies of eczema might be questioned regarding the homogeneity of their patient populations. Realizing the need for better diagnostic criteria, we have recently proposed the following outline as a means for more uniform assessment and communication by investigators studying this disease:

Diagnostic Criteria for Atopic Dermatitis

Absolute Features—

Must Have Each of the Following:

1. Pruritus
2. Typical morphology and distribution:
   a. Flexural lichenification in adults
   b. Facial and extensor involvement in infancy
3. Tendency toward chronic or chronically-relapsing dermatitis

plus

Two or More of the Following Features:

1. Personal or family history of atopic disease (asthma, allergic rhinitis, atopic dermatitis)
2. Immediate skin test reactivity
3. White dermographism and/or delayed blanch to cholinergic agents
4. Anterior subcapsular cataracts

or

Four or More of the Following Features:

1. Xerosis/ichthyosis/hyperlinear palms
2. Pityriasis Alba
3. Keratosis pilaris
4. Facial pallor/infraorbital darkening
5. Dennie-Morgan infraorbital fold
6. Elevated serum-IgE
7. Keratoconus
8. Tendency toward nonspecific hand dermatitis
9. Tendency toward repeated cutaneous infections

Perhaps nowhere is confusion more rampant than in speculations regarding the pathogenesis of atopic dermatitis. Through the years, etiologic discussions have focused mainly around physiologic and immunologic considerations. Physiologic defects quickly become obvious to anyone who observes the skin of atopic dermatitis patients. This skin is extremely dry and pruritic; low thresholds for induced pruritus have been objectively demonstrated.[2] Signs of abnormal cutaneous vasoreactivity include decreased digital skin temperature,[3] white dermographism, and delayed blanch response to cholinergic agents.[4] Based on observations of similarly altered pharmacologic reactivity among asthmatics, as well as studies in animals, Szentivanyi[5] proposed the β-adrenergic theory of atopic disease in 1968. He suggested that the heightened sensitivity of atopics to acetylcholine and other agents could be due to a blockade of β-adrenergic receptors in tissues. Thus, he considered atopy a disease of disordered physiologic and pharmacologic reactivity. Immunologic reactions would be only one group along with infectious, chemical, physical, and psychic stimuli that might trigger the pathologic hyperreactivity. Szentivanyi's theory has stimulated considerable research that will be discussed below.

Immunologic associations with atopic dermatitis have long been appreciated. The frequent personal and familial association with asthma and allergic rhinitis originally sug-

gested that atopic dermatitis might also be due to reactions between antigen and tissue fixed, reaginic antibodies. We know, however, that we cannot clearly classify the lesions of atopic dermatitis as the urticarial wheals of type 1 hypersensitivity nor any other of the four commonly accepted types of immunologic reactions.

Immunologic studies relating to atopic dermatitis can be roughly categorized into the following: (*a*) abnormalities of humoral immunity; (*b*) defects of cell-mediated immunity; (*c*) associations with immunodeficient states; and (*d*) studies relating to the cyclic nucleotide system. In discussing each of these topics, we will attempt to focus on areas where abnormalities of one system might interrelate to abnormalities in others.

ABNORMALITIES OF HUMORAL IMMUNITY

Early studies of serum immunoglobulins recorded no clear differences between normal and atopic populations,[6-8] though a subsequent report suggested an increased frequency of IgA deficiency among a population of 641 atopic patients.[9] Taylor et al[10] studied the infant offspring of atopic parents and showed that transient deficiency of IgA at age 3 months was associated with increased risk of developing atopy within the first year. The authors presented the interesting hypothesis that this transient letdown of a mucosal IgA barrier against antigens could lead to inappropriate stimulation of IgE-producing lymphocytes and consequent development of atopy. A recent report recorded increased serum-IgG and IgM along with decreased IgD levels in a group of adults with atopic dermatitis.[11]

Perhaps the best known immunologic abnormality in atopic dermatitis relates to reaginic or cytotropic antibodies. It has been repeatedly shown that there is a higher than normal incidence of immediate wheal (type 1) reactions to common environmental allergens administered by scratch or intradermal routes. In Rajka's series,[12] nearly 80% of patients had positive responses, and Stone et al[13] noted that patients with a high percentage of positive responses tended to have more severe atopic dermatitis. These associations may merely be incidental to the disease, however, since a number of patients do not react, at least to a standard battery of antigens. Considerable doubt was cast on the role of skin sensitizing antibodies in the pathogenesis of atopic dermatitis in 1962 when Peterson et al[14] reported four boys with congenital x-linked agammaglobulinemia and typical flexural eczema. Skin tests with over 200 antigens failed to demonstrate wheal and flare sensitivity in these patients. Conversely, among atopic dermatitis patients with positive type 1 hypersensitivity, there is no evidence that the immediate wheal reactions lead to the changes we recognize in the skin as atopic dermatitis. This is not to say, however, that related mechanisms may not be operative; it is, perhaps, useful to recall Engman's report in which a child with confirmed wheat hypersensitivity was challenged orally with that antigen. Half his body was protected by dressings, and following wheat ingestion, atopic dermatitis lesions appeared only on the unprotected areas, apparently mediated by a reaction causing severe pruritus and subsequent traumatization.[15]

In spite of doubts as to its relevance in the pathogenesis of atopic dermatitis, reagin has received considerable attention in the years since Ishizaka identified this antibody as a distinct class called immunoglobulin E.[16]

Clinical studies soon established the presence of high serum IgE levels in patients with asthma,[17] allergic rhinitis,[18] parasitosis,[19] and Wiskott-Aldrich syndrome.[20] In 1969, Juhlin et al[21] reported elevated serum IgE levels in 23 of 28 patients with atopic dermatitis. These findings have been confirmed repeatedly with studies showing the following: (1) Levels tend to be highest in patients with atopic dermatitis and coexisting allergic respiratory disease (ARD)[22]; (2) The degree of elevation roughly corresponds to the severity of skin disease[12,22-24]; and (3) serum IgE levels may remain high in spite of resolution of the dermatitis.[25]

The recent report by Ohman and Johansson[11] suggested that serum IgE levels may not be elevated in patients with pure atopic dermatitis (ie, in the absence of ARD). If confirmed, this finding would present impressive evidence against a role for IgE in the pathogenesis of atopic dermatitis. The authors admitted, however, that their study suffered from lack of a concomitant normal adult control group. The recent study by Jones et al[22] showed significantly elevated serum IgE levels in patients with pure atopic dermatitis.

The two studies clearly agree that serum IgE levels are highest in combined atopic dermatitis with ARD and relatively low in atopic dermatitis alone. This fact, plus the presence of elevated IgE levels in dermatoses such as dyshidrosis, acne,[24] and bullous pemphigoid[26] may reflect a purely coincident association between atopic dermatitis and serum IgE. Certainly, every study has demonstrated patients with atopic dermatitis and normal serum IgE levels.

Interpretation of all these studies is clouded, however, by the fact that IgE is a tissue-fixing antibody and hence, serum levels do not necessarily indicate total body levels. IgE-bearing B lymphocytes have been reported in a patient with atopic dermatitis and agammaglobulinemia,[27] and a recent study demonstrated local production of antigen-specific IgE in respiratory mucosa without evidence of this antibody in the serum.[28] Skin IgE levels in patients with atopic dermatitis may be elevated independent of serum levels.[29]

At the present time, the role of IgE in the pathogenesis of atopic dermatitis remains unclear. Increased serum IgE can only be considered as one of the features of atopic dermatitis, possibly reflecting dysfunctional control of the immunoglobulin producing cells. As a practical test, serum IgE levels offer little aid to either diagnosis or prognosis in clinical situations.

DEFECTS OF CELL-MEDIATED IMMUNITY IN ATOPIC DERMATITIS

In addition to abnormalities of humoral immunity in atopic dermati-

tis, several lines of evidence attest to dysfunctional cell-mediated immunity (CMI) as well. Perhaps the most obvious is the susceptibility of these patients to unusually severe cutaneous infections, especially viral conditions such as disseminated vaccinia (eczema vaccinatum) and herpes simplex (eczema herpeticum). Atopic patients may also have an increased susceptibility to warts as was recently suggested by Currie et al.[30] We have also been impressed by the association between chronic dermatophyte infection and atopic disease. A study of 20 patients with unusually extensive and chronic *Trichophyton rubrum* infections revealed that 15 of the group demonstrated immediate wheal reactivity to intradermal trichophytin and ten of the 20 had clinical or historical evidence of atopy.[31] Occasional patients in our series have noted exacerbations of their chronic fungal infections coincident with atopic dermatitis flares.

Another area of study is related to delayed hypersensitivity reactions in atopics. For many years, the situation has been confused because some investigators noted an increased incidence of contact allergy in patients with atopic dermatitis[32,33] with particular emphasis on neomycin sensitivity.[34,35] In retrospect, these findings may simply represent the high frequency of exposure to sensitizing topical medications among atopic dermatitis patients. The actual situation with regard to contact allergy was predicted in 1937 by Rostenberg and Sulzberger who noted a surprisingly low incidence of positive patch tests in atopic dermatitis patients.[36] These findings have been amply confirmed and the bulk of evidence favors the concept that atopics are no more likely to develop allergic contact dermatitis than are normals.[37]

Several studies have indicated that atopic patients may actually have a decreased rate of sensitization to experimentally applied antigens. This was perhaps first enunciated by Becker (in a discussion of Rostenberg and Sulzberger's 1937 paper)[36] who cited the difficulty of obtaining positive patch test reactions to poison ivy extract in his patients with atopic dermatitis. In 1966, Palacios et al[38] reported that while atopic patients had normal humoral antibody responses to antigens, they were less easily sensitized to dinitrochlorobenzene (DNCB) than were normal subjects. More recently, Jones et al[39] noted that patch tests revealed 61% of normal controls were sensitive to *Rhus* but only 15% of atopics. A second testing of those patients who were negative to the first test showed that a third of the normals had been sensitized by that first test while only 6% of atopic dermatitis patients converted.

Atopic dermatitis-like skin lesions are a common manifestation of Wiskott-Aldrich syndrome, a disease with severely depressed cell mediated immunity. In 1972, Lobitz et al[40] described two atopic dermatitis patients with severely depressed CMI. These patients showed no delayed cutaneous hypersensitivity to natural antigens nor could they be sensitized to DNCB. Cultured lymphocytes from these patients showed abnormally low responses to phytohemagglutinin (PHA) though one patient showed normalization of this function during periods of remission. Histologic evaluation of these patients' lymphoid tissue revealed depletion of paracortical T cell areas and markedly hyperplastic B cell dependent areas. These latter areas showed a proliferation of IgE-bearing cells as indicated by immunofluorescence microscopy. Increased numbers of IgE-bearing leukocytes were also noted in the peripheral blood of these patients. Normally, immunoglobulin-bearing B cells comprise only approximately 20% of the lymphocytes in peripheral blood and less than 1% of those stain with fluoresceinated anti-IgE. A subsequent report by Cormane et al[41] demonstrated that 14% to 31% of the lymphocytes from ten atopic dermatitis patients stained for IgE. As with serum IgE, the pathologic significance of these findings remains unclear.

Because of the considerable evidence for depressed cell-mediated immunity in atopic dermatitis, and because the T lymphocyte is known to mediate CMI, we quantitated T cell levels using the rosette-forming cell (RFC) assay.[42] We found that patients with moderate to severe atopic dermatitis had significantly decreased RFC levels compared to normal (Fig 1).[43] Similar findings have since been noted by two other groups.[44,45] When we compared RFC levels with serum IgE levels, a rough inverse correlation was noted—ie, patients with the higher IgE levels tended to have lower numbers of circulating rosette-forming T cells. Furthermore, when normal lymphocytes were preincubated in serum from these atopic patients, the rosette-forming capacity was reduced; other studies using this assay provided indirect evidence that inhibition of rosette formation was due to IgE in the serum.[46] The possibility that IgE may produce a direct influence on T cells is an intriguing but not yet proven hypothesis.

It is important in this review to give some perspective to dysfunctional cell-mediated immunity in atopic dermatitis. Considerable confusion has arisen as a result of the finding of depressed lymphocyte function in patients with severe disease. Most atopic dermatitis patients manifest delayed cutaneous hypersensitivity and have normal in vitro leukocyte responses. In our study of 14 patients with moderate to severe atopic dermatitis, in vitro lymphocyte transformation was normal in seven of the patients. In the other seven patients, all with severe erythrodermatous involvement, not only was lymphocyte transformation to PHA and concanavalin-A depressed, but these patients also had markedly depressed chemotaxis of both the polymorphonuclear (PMN) and monocyte series. In three of the patients, chemotactic function was noted to improve markedly within as little as 48 hours as the patient's severe dermatitis regressed.[47] Preliminary studies indicate that an inhibitory factor in the plasma of atopic dermatitis patients may be responsible for the leukocyte dysfunctions seen in these patients during severe flares of their disease.[48] These factors of timing and severity of disease no doubt account for the variable in vitro findings in several recent studies of CMI in atopic dermatitis.[45,49-51] From

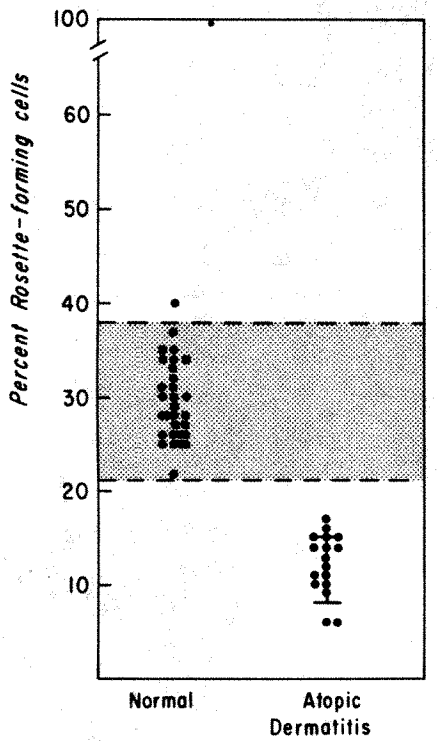

Fig 1.—Percentage of rosette-forming cells among isolated peripheral blood lymphocytes from normal subjects and atopic dermatitis patients. Shaded area represents the normal range (mean ± standard deviation).

our studies, it appears that each of the three cell types most directly involved with host resistance to infection may be dysfunctional in atopic dermatitis but that these functional abnormalities may be detectable only during periods of severe disease.

The problem of cutaneous anergy among atopics is likewise somewhat confusing. Some patients with atopic dermatitis fail to respond to a battery of naturally occurring antigens such as tuberculin, trichophytin, candidin, and streptokinase-streptodornase, yet may have normal in vitro lymphocyte responses to nonspecific mitogens.[47] The most likely explanation is that the in vitro studies assess only limited aspects of the total immune system while intradermal stimulation tests the intactness of the entire mechanism. The possibility must be considered, however, that anergy in these patients is due to a local, cutaneous defect. At the present time, there is simply not enough evidence to allow comment on the two possibilities.

Early in vitro studies in patients with atopic dermatitis raised the question of whether the disease might be an autosensitization to skin. A report by Hashem et al, in 1963,[52] suggested that cell-free skin extracts were capable of causing transformation of autologous lymphocytes cultured from the blood of patients with atopic dermatitis. Two subsequent studies[53,54] failed to confirm this finding. Using a somewhat different approach, Japanese investigators have suggested that some patients with atopic dermatitis may have cell-mediated reactivity against human dander,[55] but these studies are preliminary and await amplification.

RELATIONSHIP BETWEEN ATOPIC DERMATITIS AND IMMUNODEFICIENCY DISEASES

The association between immune deficiency and eczema similar to atopic dermatitis has been appreciated for many years. The x-linked Wiskott-Aldrich syndrome with eczema, thrombocytopenia, and recurrent infections is perhaps the best known of these.[56,57] Atopic dermatitis was noted in two of 22 patients with ataxia telangiectasia; a seborrheic-type dermatitis is a more common cutaneous feature in these patients.[58] Peterson[14] documented atopic dermatitis in four of 23 patients with x-linked agammaglobulinemia.

A condition receiving increasing attention in recent years is the hyper-immunoglobulin-E syndrome of Buckley.[59] In addition to elevated serum IgE levels, these patients have recurrent cutaneous staphylococcal infections, frequent candidosis, and many have an eczema similar to atopic dermatitis.[59-61] The basic defect is unclear; delayed hypersensitivity responses may be normal or abnormal. It appears that patients with this syndrome are a functionally heterogeneous group with a few constant features. Many of these patients have defective in vitro chemotaxis of PMNs[60] and/or monocytes.[62] In their chemotaxis studies, Hill and Quie[60] were unable to inhibit normal PMN migration with serum or plasma from hyper-IgE patients. These findings are at variance with our recent observations in patients with atopic dermatitis and may reflect basic pathogenetic differences in the two conditions or simply different technical approaches for assessing plasma inhibition. These authors did put forth the intriguing hypothesis that antigen-IgE interaction with leukocytes could cause release of histamine that in turn might account for the chemotactic defects which they observed. Their studies showed that histamine inhibited normal PMN chemotaxis, and more recent studies have shown similar depression of mitogen-induced lymphocyte blastogenic transformation.[62] High levels of blood and skin histamine could well account for the erythema and pruritus seen in patients with hyperimmunoglobulinemia-E and atopic dermatitis; likewise, at the same time, histamine would correlate with the elevated serum IgE levels and the dysfunctional chemotaxis and lymphocyte transformation we have observed in patients. Proof of this hypothesis awaits direct demonstration of elevated plasma histamine effects on leukocytes.

Increased serum IgE in combination with depressed CMI and eczema has been noted not only in Wiskott-Aldrich syndrome[20] and in the hyper-IgE syndrome, but also in at least one case of thymic alymphoplasia.[63] The DiGeorge syndrome[64] and some cases of Nezelof syndrome[65] likewise present with a combination of increased IgE and decreased CMI responsiveness, though eczema is generally not a feature of these conditions. Serum IgE is elevated in patients with selective IgA deficiency but so is the incidence of atopy[66]; among nonatopic IgA-deficient patients, IgE levels are normal.[65] Some of these patients have decreased rosette-forming T cells[67] and impaired lymphocyte responsiveness to PHA.[68] Also, as mentioned earlier, transient IgA deficiency in early infancy may be associated with later development of eczema and abnormally high serum IgE levels.[10]

In general, then, serum IgE levels are elevated in conditions with impaired CMI and frequently these in turn are associated with atopic dermatitis. The varied associations between atopic dermatitis, hyper-IgE, and impaired CMI strongly suggest a human

correlate to animal studies reported by Tada et al.[69] These workers showed abnormally high and prolonged IgE production in T cell depleted rats. Infusion of carrier-specific, syngeneic T lymphocytes resulted in a rapid return to normal IgE levels. Absence of a certain T cell subpopulation in humans with atopic dermatitis could account for the laboratory findings in these patients of elevated serum IgE, decreased rosette-forming T-cells, and impaired cellular immune responses. It is difficult, however, to outline a coherent relationship between these lymphocyte defects and the changes seen in the skin of atopic dermatitis patients.

A fascinating area of speculation in this regard is the possibility that human T cells and epidermal cells may have common characteristics. This suggestion is based on the fact that Hassall's corpuscles of the thymus appear to contain cornified squamous cells.[70] Also, the nude mouse lacks both normally differentiated T lymphocytes and hair,[71] and murine T cells and epidermal cells share specific membrane antigenic determinants.[72] It is possible that a common defect might account for the abnormalities seen in epidermal cells and T lymphocytes of patients with atopic dermatitis.

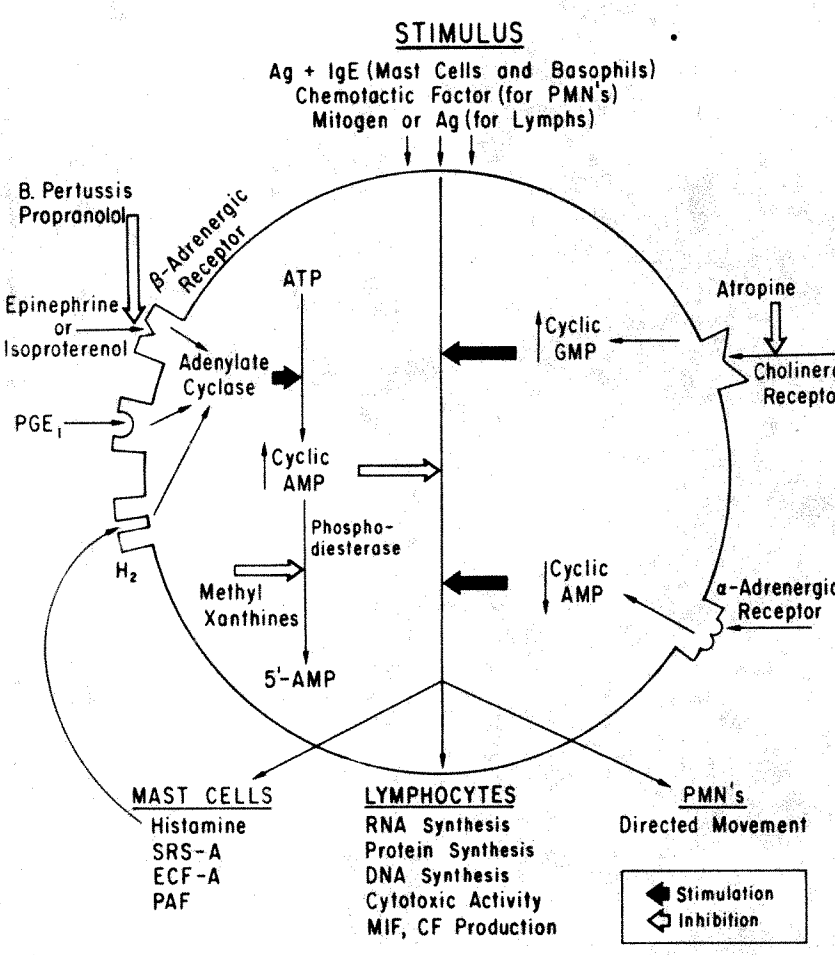

Fig 2.—Diagrammatic representation of pathways by which pharmacologic mediators might act on mast cell, lymphocyte and PMN leukocyte membrane receptors to alter intracellular cyclic nucleotides which in turn may either enhance or inhibit the function of those cells. Abbreviations include the following: Ag, antigen; PGE_1, prostaglandin E_1; SRS-A, slow-reacting substance of anaphylaxis; ECF-A, eosinophil chemotactic factor of anaphylaxis; PAF, platelet activating factor; MIF, migration inhibitory factor; CF, chemotactic factor.

ALTERED PHARMACOLOGIC ACTIVITY IN ATOPIC DERMATITIS

Increased sensitivity of atopics to histamine and cholinergic agents has been appreciated for many years. Patients with atopic dermatitis show greater than normal erythema in response to parenteral histamine, and interestingly, this effect occurs mainly in the knee and elbow flexures, sites of predilection for atopic dermatitis.[73] Intradermal injection of cholinergic agents produces a delayed blanch response in atopic dermatitis patients,[4] a phenomenon thought to be due either to excessive vasoconstriction,[74,75] or to a sudden increase of vascular permeability.[76,77] Acetylcholine also produces increased sweat production in atopic dermatitis patients,[78] although this may not be clinically apparent because these patients appear to have a defective sweat delivery system.[79] The β-adrenergic blocking agent propranolol causes enhanced acetylcholine-induced sweat production in normals but has no effect on atopics.[80] Patients with atopic dermatitis also appear to have increased adrenergic sensitivity of cutaneous vasculature.[81-83]

Most of these abnormalities could be explained by Szentivanyi's β-adrenergic blockade theory. Increased cholinergic and α-adrenergic sensitivity could be the result of an inadequate β-adrenergic counterbalance. This concept has stimulated considerable investigation of isolated tissues in vitro with regard to pharmacologic influences on cell function, proliferation, and cyclic-adenosine monophosphate (AMP) levels.

Bullough[84] showed that β-adrenergic stimulation with catecholamines inhibited epidermal cell division and subsequent studies indicated that cyclic AMP decreases epidermal mitosis.[85] Carr et al[86] compared DNA synthesis in cultured epidermis from normal subjects and patients with atopic dermatitis. They noted no difference in untreated cultures, but catecholamines inhibited DNA synthesis of normal cells while having no effect on epidermal cells from atopics. Epidermal cyclic AMP assays recorded no differences between normals and atopics, either in resting cultures or in isoproterenol-treated cultures.[87] These studies were in accord with others that failed to show any abnor-

mality of adenyl cyclase,[88] phosphodiesterase,[89] or cyclic AMP-dependent protein kinase[90] in the skin of patients with atopic dermatitis. Likewise, levels of enzymes related to glucose metabolism were normal in isolated sweat glands of atopic patients.[91]

Several investigators have elected to study the isolated leukocyte populations in atopics. Decreased adenyl cyclase responses to β-adrenergic agents have been noted in asthma patients.[92,93] Parker and Eisen, in 1972,[94] presented data showing a subnormal cyclic-AMP response to isoproterenol in mixed leukocytes from patients with atopic dermatitis, and similar findings have been noted in purified lymphocytes by Reed et al.[87] This latter group has likewise noted a diminished lymphocyte cyclic AMP response to isoproterenol but a normal response to prostaglandin E-1.[87] These authors suggest that, while atopics have intact adenyl cyclase, phosphodiesterase, and protein kinase systems, they may have a defect antecedent to activation of adenyl cyclase and specific for the β-adrenergic receptor. Incomplete evidence suggests that a factor in atopic serum may confer the subnormal cyclic AMP response to β-adrenergic agonists in these various cell systems.[95]

A considerable amount of research has focused, in recent years, on the relationship of the cyclic AMP system to normal function of those cells involved with mediation of immune responses; the mast cell, basophil, lymphocyte, and PMN (Fig 2). This interrelationship has been especially well elucidated in studies of mast cells and basophils. When two or more IgE molecules on the surface of these cells are bridged by either specific divalent antigen or by antibody to IgE, an energy requiring sequence is activated leading to release of histamine and other inflammatory mediators. The β-adrenergic agonists, PGE-1 and even histamine, act via distinct receptors through adenyl cyclase to cause increased levels of intracellular cyclic AMP which in turn has an inhibitory influence on release of histamine, etc. Conversely, cholinergic agents, act via less well-defined pathways to decrease cyclic AMP and enhance mediator release, as do agents acting on α-adrenergic receptors.[96-99]

Ishizaka and Ishizaka[100] compared histamine release from leukocytes of normals and atopics under control situations. They found the number of IgE-binding sites per basophil similar in the two groups, and under saturation conditions, there was no difference in number of IgE molecules per basophil. The atopic group did, however, tend to have a lower threshold of maximum histamine release by anti-IgE. These studies suggested that the number and binding affinity of IgE molecules probably determine the sensitivity of basophils to allergen while the percentage of histamine release is dependent on regulatory intracellular systems. An imbalance caused by β-adrenergic blockade could account for accentuated release of inflammatory mediators from mast cells and basophils of atopics.

Leukocyte studies have indicated that elevated cyclic-AMP levels are associated with inhibition of cytotoxic activity,[101] immunoglobulin synthesis,[102] and DNA synthesis[103,104] in lymphocytes and decreased chemotaxis[105] by PMNs. As mentioned above, measurably decreased lymphocyte DNA synthesis along with monocyte and PMN chemotaxis is seen in patients with severe atopic dermatitis and plasma from such patients will confer these functional defects on normal leukocytes. Since we must assume an ultimate cellular source for such an inhibitory factor, it is conceivable that loss of cellular control (ie, β-adrenergic blockade) could account for inappropriate production of an inhibitory mediator such as histamine by mast cells along with overproduction of IgE by B lymphocytes. Such an hypothesis fails, however, to clearly account for the decreased numbers of rosette-forming T cells in the blood of atopic dermatitis patients, though this phenomenon could simply reflect a differentiative or maturational defect among these cells. Extrapolation from studies on this subject suggests that the quantity of undifferentiated or null cells (lymphocytes with neither B cell or T cell characteristics) is increased in patients with atopic dermatitis.[44,45]

Immunopharmacologic studies in atopy are very much in their infancy, but these shreds of preliminary evidence predict an exciting and potentially fruitful realm of investigation in coming years.

In summary, atopic dermatitis is a disease characterized by abnormalities related to both type 1 and type 4 immune responses, yet the skin lesions cannot be classified under either of these reaction types. The disease is difficult to define; diagnosis depends on a combination of morphologic, distributional, and historical features.

Skin lesions typical of atopic dermatitis are seen in a number of immune deficiency conditions, especially those characterized by depressed cell-mediated immunity, elevated IgE production, and in some instances, IgA deficiency suggesting a common disorder in the ontogeny of immunoglobulin-producing cells. Defective T lymphocyte mediation of the B lymphocytes producing these immunoglobulins may explain the combined cellular and humoral abnormalities observed. Homologies between T cells and epidermal cells could account for the combined immunologic and cutaneous defects seen in atopic dermatitis.

Recent evidence suggests the possibility of an even more basic disorder in atopic dermatitis. Preliminary studies indicate that a factor in serum from atopic dermatitis patients can depress in vitro leukocyte function and inhibit epidermal cell cyclic AMP responses to β-adrenergic agonists. Such a factor could account for many of the indications of β-adrenergic blockade seen in patients with atopic dermatitis. Considerably more work will be necessary to identify the primary defect responsible for the disease which presents as atopic dermatitis.

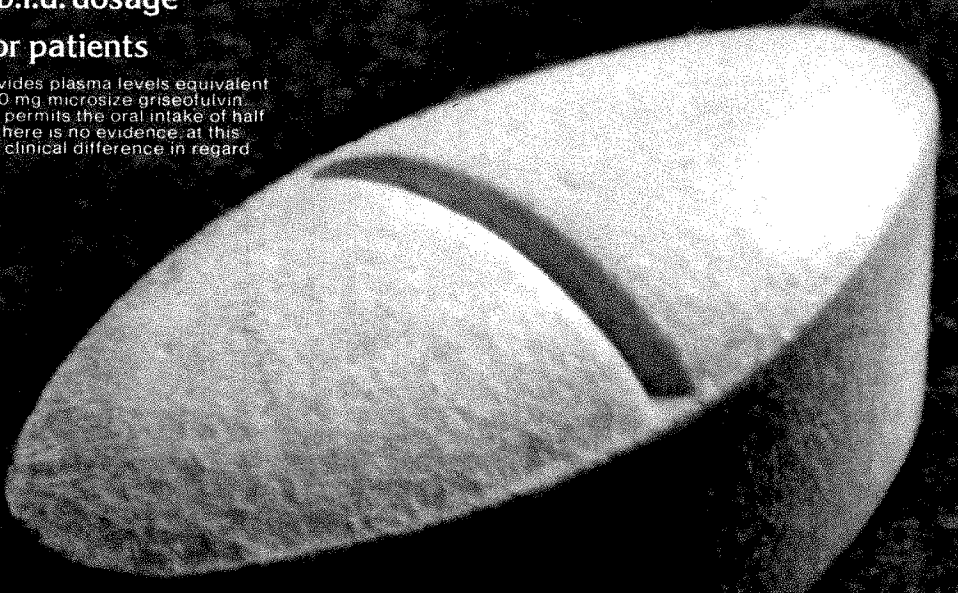
CUT THE GRISEOFULVIN DOSE IN HALF

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg

For fungal infections sensitive to griseofulvin

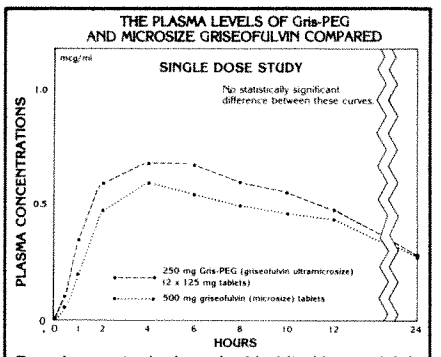
- Only half the dose required*
- Absorption nearly complete without fatty meals
- Once-a-day or b.i.d. dosage
- Reduced cost for patients

*250 mg of Gris-PEG® provides plasma levels equivalent to those obtained with 500 mg microsize griseofulvin. This improved absorption permits the oral intake of half as much griseofulvin but there is no evidence at this time that this confers any clinical difference in regard to safety or efficacy.

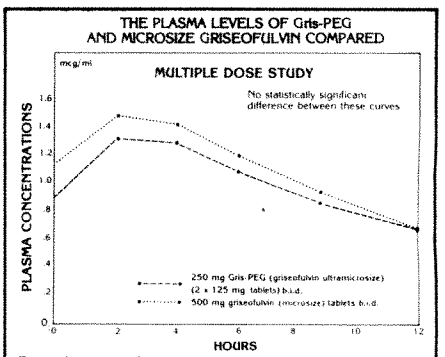


Dorsey LABORATORIES
Division of Sandoz, Inc.
LINCOLN, NEBRASKA 68501

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
The ½ dose griseofulvin.



Based on a single dose double-blind bioavailability study conducted in 24 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels. There is no significant difference between peak plasma levels, times to peak, and areas under the curve. Gas chromatographic assay.



Based on a double-blind multiple dose steady state crossover bioavailability study conducted in 17 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels obtained on days 9, 11 and 13. There is no significant difference between times to peak, peak plasma levels, and areas under the curve. Gas chromatographic assay.

DESCRIPTION

Griseofulvin is an antibiotic derived from a species of *Penicillium*.

Gris-PEG is an ultramicrocrystalline solid-state dispersion of griseofulvin in polyethylene glycol 6000.

Gris-PEG tablets differ from griseofulvin (microsize) tablets USP in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsize griseofulvin.

ACTION

Microbiology: Griseofulvin is fungistatic with *in vitro* activity against various species of *Microsporum, Epidermophyton* and *Trichophyton*. It has no effect on bacteria or other genera of fungi.

Human Pharmacology: The peak plasma level found in fasting adults given 0.25 g of Gris-PEG occurs at about four hours and ranges between 0.37 to 1.6 mcg/ml.

Comparable studies with microsize griseofulvin indicated that the peak plasma level found in fasting adults given 0.5 g occurs at about four hours and ranges between 0.44 to 1.2 mcg/ml.

Thus, the efficiency of gastrointestinal absorption of the ultramicrocrystalline formulation of Gris-PEG is approximately twice that of conventional microsized griseofulvin. This factor permits the oral intake of half as much griseofulvin per tablet but there is no evidence, at this time, that this confers any significant clinical differences in regard to safety and efficacy.

Griseofulvin is deposited in the keratin precursor cells and has a greater affinity for diseased tissue. The drug is tightly bound to the new keratin which becomes highly resistant to fungal invasions.

INDICATIONS

Gris-PEG (griseofulvin ultramicrosize) is indicated for the treatment of the following ringworm infections.

Tinea corporis (ringworm of the body)
Tinea pedis (athlete's foot)
Tinea cruris (ringworm of the thigh)
Tinea barbae (barber's itch)
Tinea capitis (ringworm of the scalp)
Tinea unguium (onychomycosis; ringworm of the nails)

when caused by one or more of the following genera of fungi:

Trichophyton rubrum
Trichophyton tonsurans
Trichophyton mentagrophytes
Trichophyton interdigitalis
Trichophyton verrucosum
Trichophyton megnini
Trichophyton gallinae
Trichophyton crateriform
Trichophyton sulphureum
Trichophyton schoenleini
Microsporum audouini
Microsporum canis
Microsporum gypseum
Epidermophyton floccosum

NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.

The use of the drug is not justified in minor or trivial infections which will respond to topical agents alone.

Griseofulvin is *not* effective in the following:

Bacterial infections
Candidiasis (Moniliasis)
Histoplasmosis
Actinomycosis
Sporotrichosis
Chromoblastomycosis
Coccidioidomycosis
North American Blastomycosis
Cryptococcosis (Torulosis)
Tinea versicolor
Nocardiosis

CONTRAINDICATIONS

This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.

WARNINGS

Prophylactic Usage: Safety and Efficacy of Griseofulvin for Prophylaxis of Fungal Infections Has Not Been Established.

Animal Toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.

In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.

Usage in Pregnancy: The safety of this drug during pregnancy has not been established.

Animal Reproduction Studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.

Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

PRECAUTIONS

Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic and hematopoietic, should be done.

Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.

Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.

Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.

Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

ADVERSE REACTIONS

When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion and impairment of performance of routine activities.

Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.

When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

DOSAGE AND ADMINISTRATION

Accurate diagnosis of the infecting organism is essential. Identification should be made either by direct microscopic examination of a mounting of infected tissue in a solution of potassium hydroxide or by culture on an appropriate medium.

Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. Representative treatment periods are—*tinea capitis*, 4 to 6 weeks; *tinea corporis*, 2 to 4 weeks; *tinea pedis*, 4 to 8 weeks; *tinea unguium*—depending on rate of growth—fingernails, at least 4 months; toenails, at least 6 months.

General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required particularly in treatment of *tinea pedis*. In some forms of athlete's foot, yeasts and bacteria may be involved as well as fungi. Griseofulvin will not eradicate the bacterial or monilial infection.

An oral dose of 250 mg of Gris-PEG (griseofulvin ultramicrosize) is biologically equivalent to 500 mg of griseofulvin (microsized), USP (see ACTION Human Pharmacology).

Adults: A daily dose of 250 mg will give a satisfactory response in most patients with *tinea corporis, tinea cruris* and *tinea capitis*. One 125 mg tablet twice per day or two 125 mg tablets once per day is the usual dosage. For those fungal infections more difficult to eradicate such as *tinea pedis* and *tinea unguium*, a divided daily dose of 500 mg is recommended. In all cases, the dosage should be individualized.

Children: Approximately 5 mg per kilogram (2.5 mg per pound) of body weight per day is an effective dose for most children. On this basis, the following dosage schedule for children is suggested:

Children weighing over 25 kilograms (approximately 50 pounds)—125 mg to 250 mg daily.

Children weighing 15-25 kilograms (approximately 30-50 pounds)—62.5 mg to 125 mg daily.

Children 2 years of age and younger—dosage has not been established.

Dosage should be individualized, as is done for adults. Clinical experience with griseofulvin in children with *tinea capitis* indicates that a single daily dose is effective. Clinical relapse will occur if the medication is not continued until the infecting organism is eradicated.

HOW SUPPLIED

Gris-PEG (griseofulvin ultramicrosize) Tablets (white) differ from griseofulvin (microsize) tablets (USP) in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsized griseofulvin. Two 125 mg tablets of Gris-PEG are biologically equivalent to 500 mg of microsized griseofulvin. In bottles of 100 and 500 scored, film-coated tablets.

Dorsey LABORATORIES
Division of Sandoz, Inc. • LINCOLN, NEBRASKA 68501

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

Patients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—particularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

LOROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

(benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%) (benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%, hydrocortisone ½%)

- Contains the proved synergistic bactericidal combination of benzoyl peroxide and chlorhydroxyquinoline (300% greater antibacterial activity[1]) — which topically reduces C. Acnes *within* comedones[2]
- LOROXIDE-HC® effectively treats papular, pustular and cystic acne[3] — a favorable response has been reported in 75% of patients in as short a period as two weeks[4]
- Ideal therapy providing "all day," penetrating antimicrobial activity with controlled drying and desquamation — at school, work or play.
- No sun-sensitizing properties — no need to restrict your patient's outdoor activities or eliminate the known benefits of natural UV exposure.
- *The only* adjustable tint-intensity benzoyl peroxide lotions available.
- Replaces and helps to prevent abuse with over-the-counter cosmetics.
- For *day-long control* of all grades of acne vulgaris.
- Lesion-masking base helps to eliminate the..."natural but distorted feelings that other people perceive him as 'acne with a person attached rather than as a person who happens to have acne'."

LOROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

DESCRIPTION: Loroxide Acne Lotion contains (as dispensed) benzoyl peroxide 5.5%, and chlorhydroxyquinoline 0.25%; incorporated in a water washable lotion consisting of purified water, propylene glycol, hydroxyethylcellulose, caramel color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, silica, kaolin, talc and titanium dioxide, with "Dermik Color Blender™" supplied separately.

Loroxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.5% and chlorhydroxyquinoline 0.25% incorporated in a lotion identical to Loroxide Lotion (see above).

Actions: Provides keratolytic, peeling and drying action.

Indications: An aid in the treatment of acne and oily skin.

Contraindications: This product is contraindicated for use by patients having known hypersensitivity to hydrocortisone, benzoyl peroxide, chlorhydroxyquinoline or any other component of this preparation. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia.

Warning — Usage in Pregnancy: Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established. Therefore, they should not be used extensively, or in large amounts or for prolonged periods of time on pregnant patients.

Precautions: For external use only. Keep away from eyes. If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Do not add any other medicaments or substances to this lotion unless specifically directed by physician to do so. Patients should be observed carefully for possible local irritation or sensitization during long-term topical therapy. Apply with caution on neck and/or other sensitive areas. There may be a slight, transitory stinging or burning sensation on initial application which invariably disappears on continued use. Ultraviolet and cold quartz light should be employed in lesser amounts, as this lotion is keratolytic and drying. Harsh, abrasive cleansers should not be used simultaneously with this lotion. Colored or dyed garments may be bleached by the oxidizing action of benzoyl peroxide. Chlorhydroxyquinoline may cause temporary light-yellowish skin staining in rare cases. Keep out of the reach of children.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneiform eruptions, and hypopigmentation. The sensitizing potential of benzoyl peroxide and chlorhydroxyquinoline are low, but they can, on occasion, produce allergic reaction. Occurrence of excessive redness or peeling indicates that the amount and frequency of application should be reduced.

Directions: Shake well before using. Apply a small quantity to affected areas with light massaging 1 to 3 times daily, or in accordance with the physician's directions.

(Important information directed to the Pharmacist: At time of dispensing, add contents of vial* to the bottle. Shake well and/or stir with a glass rod to insure a uniform dispersion. Place expiration date of three (3) months on bottle label.)

*"Benzie-Pak" vials contain a mixture of benzoyl peroxide 35% and calcium phosphate 65%.

Net weight of each vial is 3.8 grams.

How Supplied: Bottles, 25 Gm.

Caution: Federal law prohibits dispensing without prescription.

Dermal Metastases From a Follicular Carcinoma of the Thyroid

Richard M. Auty, BSc, MD, MRCP

Cutaneous metastases from internal cancer are relatively uncommon, occurring in only two (5%) of all cases of cancer.[1,2] The carcinomas most frequently responsible for such lesions are those that produce extensive secondary deposits in the internal organs;[1] follicular carcinoma of the thyroid gland is such a tumor, producing widespread visceral lesions,[3] but no previous report of metastases to the skin in this condition has been found, to my knowledge.

From the Department of Medicine, Ahmadu Bello University, Zaria, Nigeria. Dr Auty is now with Fisons Ltd, Loughborough, Leicestershire, England.

Reprints not available.

REPORT OF A CASE

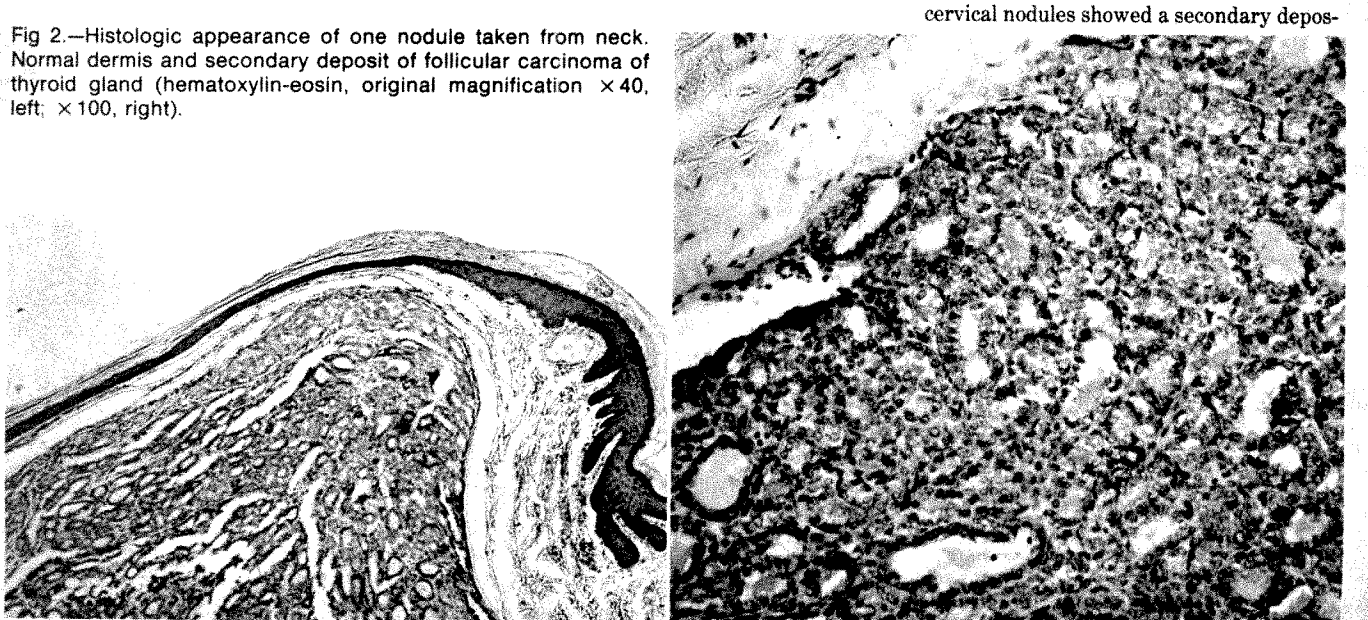
A 41-year-old Tiv man from Plateau Stage of Nigeria was first seen at Ahmadu Bello University Hospital, Zaria, in April 1976. Four years previously he had developed a painless swelling in the root of his neck, and a partial thyroidectomy was performed elsewhere. The operative specimen is now unavailable, but it was reported to show "follicular adenoma of the thyroid." The patient remained asymptomatic for two years after the operation, but in 1974 he began to develop painless nodules in the skin, first over the thyroidectomy scar, and then in the scalp, the face (including the nose), the neck, and the upper thorax.

On examination, he was a fit looking man with 26 nodules of various sizes on his head and chest (Fig 1). Each nodule was in the skin; those that were superficial were deep magenta, but the deep nodules were skin colored. All were pulsatile. The largest were in the long axis of the thyroidectomy scar (1 × 2 cm), and the smallest were hemispherical with a diameter of 0.5 cm. No lesions were found around or inside the mouth. Clinically the lesions were indistinguishable from those of Kaposi's sarcoma, as seen in northern Nigeria.

The arterial pulse was collapsing, and the blood pressure was 110/60 mm Hg. A few crepitations were audible at both lung bases. No other abnormal physical signs were detected. The chest roentgenogram showed multiple radio-opaque lesions in both lung fields, compatible with pulmonary metastases. No skeletal metastases were detected radiographically, nor were there any bony lesions underlying the skin nodules. A biopsy specimen of one of the cervical nodules showed a secondary depos-

Fig 1.—Multiple, pulsatile nodules on face and scalp, suggesting Kaposi's sarcoma.

Fig 2.—Histologic appearance of one nodule taken from neck. Normal dermis and secondary deposit of follicular carcinoma of thyroid gland (hematoxylin-eosin, original magnification ×40, left; ×100, right).



it of follicular carcinoma of the thyroid in the skin (Fig 2). The patient was treated with an initial dose of 80 μCi of radioactive iodine 125, followed four weeks later by a further dose of 150 μCi of radioactive iodine 125. He is being followed up as an outpatient.

COMMENT

Follicular carcinoma is the most malignant of the well-differentiated thyroid carcinomas (follicular carcinoma, papilliary carcinoma, and mixed carcinoma), and it has the worst prognosis at the time of diagnosis.[3] It spreads by the blood stream, and metastasis to the lungs and bones is typical.[4-6] Metastases have been found in almost every visceral organ, but not in the skin, although other malignant lesions of the thyroid are known to produce skin metastases.[5]

Gates[1] commented that tumors that produce extensive metastases to the internal organs are those most likely to metastasize to the skin. Clearly, follicular carcinoma of the thyroid falls into this category, but in her own extensive series she found only one case of "thyroid carcinoma" (type unspecified) metastasizing to the skin, and only two such cases (type again unspecified) in her review of the literature that extended back beyond 1900.

Mehregan[2] reported 22 cases of metastatic carcinoma to the skin, none from a thyroid neoplasm, and commented on his own and other workers' observation of the disproportionate frequency of lesions in the scalp. Gates[1] suggested that the apparent predilection for the scalp could be due to the vascularity and relative immobility of the skin at this site.

It appears, therefore, that this is the first documented case of metastasis to the skin by a follicular carcinoma of the thyroid.

Dr Charles Awunor-Renner gave permission to report a case admitted under his care, and Prof Eldryd H.O. Parry gave helpful advice and criticism.

Ulcerative Sarcoidosis

Report of an Unusual Case

Judith Schiffner, MD, Om P. Sharma, MD

Sarcoidosis is a systemic granulomatous disease of unknown cause that may involve almost any organ of the body. The skin is involved in approximately 25% of patients with the disease. Characteristically, the skin lesions do not ulcerate, do not become necrotic, and do not form sinuses. This report describes a patient with extensive multisystem sarcoidosis who had numerous ulcerated cutaneous plaques and nodules.

REPORT OF A CASE

A 79-year-old black woman was referred to Los Angeles County-University of Southern California Medical Center in February 1974 for evaluation of increasingly severe skin lesions. She was in excellent health until 1950, when she developed a chronic malar erythematous "butterfly eruption" and a swollen right fifth digit. Three years prior to admission, the facial lesions had become nodular and crusted. Because of the increase in number and severity of the skin lesions, as well as the apparent multisystem involvement of the process, she was referred to this institution.

On admission, the physical examination showed erythematous, ulcerated nodules and plaques over both malar areas with serous exudation and crusting. Involvement of the left upper and lower eyelids resulted in near-complete closure of the left eye (Fig 1). Granulomatous lesions were observed on mucosa of the soft and hard palate and uvula. Collapse of the septum and crusting of the nasal mucosa were also noted. The entire right fifth digit and right fourth digit about the proximal interphalangeal joint demonstrated fusiform violaceous swelling (Fig 2). There were several ulcerated nodules on the dorsum of the right wrist and forearm. The rest of the physical examination was normal.

Important laboratory data included a reversed albumin-globulin ratio and absence of complement-fixing antibodies against coccidioidomycosis and histoplasmosis. Intradermal skin testing with purified protein derivative, coccidioidin, histoplasmin, mumps antigen, *Candida* and *Trichophyton* antigens, streptokinase-streptodornase were all negative at 48 hours.

The chest x-ray film showed parenchymal linear densities in the right upper lung zone at both bases with associated calcification in the right perihilar and peritracheal nodes. X-ray films of the hands showed extensive soft-tissue swelling of the right fourth and fifth fingers with radiolucent cystic changes involving the proximal right fourth and fifth phalanges and middle phalanx of the right fifth finger. A biopsy specimen from a forearm and facial nodules showed noncaseating epithelioid granulomas (Fig 3). In certain areas substantial lymphocytic and polymorphonuclear infiltration was present. Special stains for fungi and acid-fast and pyogenic bacteria were negative. Culture of the biopsied tissue also did not grow fungi or acid-fast bacilli. Guinea pig inoculations were negative. Examination of the

Fig 1.—Erythematous, indurated nodules and plaques over both malar area and left upper eyelid. Note extensive exudation and crusting. Patient is not able to open her left eye.

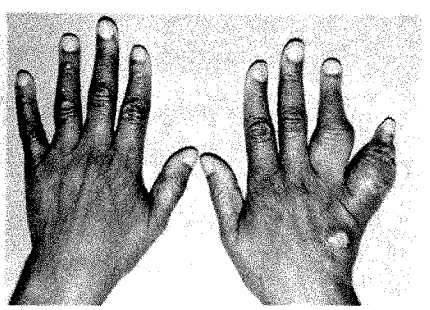

Fig 2.—Fusiform erythematous swelling with exudation and ulceration of right fourth and fifth digits.

biopsy specimens under polarized light did not show birifringent particles.

The diagnosis of sarcoidosis was made, and the patient received 500 mg of chloroquine phosphate daily. She also received weekly intralesional triamcinolone acetonide (5 mg/ml) injections to the left upper eyelid for one month with reduction of the swelling. After two months of the chloroquine therapy, there was only modest improvement, but when treatment with prednisone (15 mg daily) was added, skin lesions cleared rapidly. After ten months of therapy, the chloroquine was discontinued, and the prednisone was tapered to 5 mg daily. All skin lesions have resolved completely, leaving residual atrophic scars.

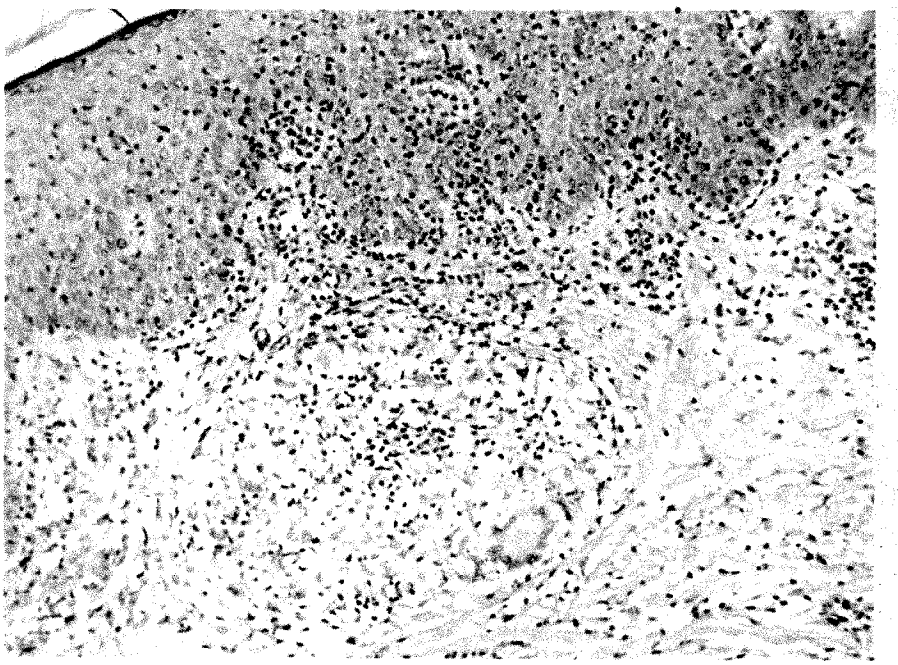

Fig 3.—Biopsy specimen of facial nodule showing discrete noncaseating epithelioid cell granuloma. Note presence of multinucleated giant cell and lymphocytes (hematoxylin-eosin, ×100).

COMMENT

The differential diagnosis of the type of skin lesions seen in this patient with histologic evidence of noncaseating granulomas includes infectious granulomas (lupus vulgaris, tertiary syphilis, deep mycosis, leprosy, swimming pool granuloma), foreign-body granulomas (silica, beryllium, and zirconium), and sarcoidosis.[1-3] The patient's history, physical examination, negative laboratory findings, and negative cultures for acid-fast bacilli and fungi effectively ruled out the existence of either the infectious or foreign-body granulomatous diseases.

The diagnosis of sarcoidosis of the skin requires the following: (1) clinical evidence of multisystem involvement or the radiologic picture consistent with sarcoidosis, or both; (2) histologic evidence of noncaseating granulomas; and (3) negative culture of tissues for acid-fast bacilli and fungi. Our patient fulfilled these criteria. In addition to her skin lesions, she showed characteristic lung, bone, and mucous membrane involvement. She was anergic to tuberculin, coccidioidin and histoplasmin, and blastomycin intradermal antigens. Her chronic indolent course of 20 years and the response to antimalarials and corticosteroids support the diagnosis of sarcoidosis.

The various skin manifestations of sarcoidosis include erythema nodosum, maculopapular rash, nodules, hypopigmented or hyperpigmented patches, scar sarcoid, lupus pernio, and plaques.[4] The presence of ulceration or necrosis of skin lesions is rare. In a few affected cases of ulcerative sarcoidosis, the legs have been a common site of ulceration. Ulcerative facial lesions of the type seen in our patient are distinctly unusual.[5,6] Another infrequent finding in this case was a mixed lymphocytic and polymorphonuclear infiltrate in certain areas.

Allergic
Dermatose

rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

Letters to the Editor

Macrocytosis and Hydroxyurea Therapy in Psoriatics

To the Editor.—Macrocytosis has been reported as a side effect of hydroxyurea therapy in psoriatics. There have been no long-term follow-up reports of patients with psoriasis who were treated with hydroxyurea.

Ten psoriatics treated with hydroxyurea six years previously were recalled for observation and blood studies. In eight patients, there was no macrocytosis. Two patients had macrocytosis; one of these patients was a chronic alcoholic and the other was taking hydroxyurea. It was thought that the macrocytosis was due to the alcoholism and current hydroxyurea medication in these patients. There was no evidence of folic acid or vitamin B_{12} deficiency. There were no long-term ill effects from hydroxyurea.

Hydroxyzine Products

To the Editor.—Patients who have urticaria are frequently treated with hydroxyzine. A number of articles have implicated sensitivity to tartrazine (FD&C Yellow No. 5) as a causative factor in cases of chronic urticaria.[1,2] It is important for the dermatologists to be aware of which hydroxyzine products are free of this dye.

I have been informed in a letter from the manufacturer of these products that hydroxyzine hydrochloride (Atarax), 25 mg and 50 mg, and all hydroxyzine (Vistaril) pamoate capsules and suspension contain tartrazine. However, hydroxyzine hydrochloride, 10 mg, 100 mg, and syrup forms, does not contain tartrazine dye.

Neonatal Anaerobic (Clostridial) Cellulitis and Omphalitis

To the Editor.—The following case is reported as an example of an unusual anaerobic infection with cutaneous findings.

Report of Case.—A 3.4-kg baby girl was delivered without incident of a 22-year-old primipara. At age 4 days, the infant was hospitalized 14 hours after the development of erythema and induration of the periumbilical skin. A brown watery discharge developed that was found to contain Gram-positive rods and cocci. The rod, identified as a clostridial species, grew as an anaerobe. *Staphylococcus aureus* and *Streptococcus faecalis* were also cultured, the former growing as a facultative anaerobe. Antibiotics failed to halt the process and after 48 hours of illness the skin in the periumbilical region had become dusky purple-gray and necrotic in appearance to a point 1.5 cm from the umbilicus. Vesicles were apparent centrally. Peripheral to the devitalized area was a 3- to 5-cm thick zone of sharply demarcated viable but faintly purpuric skin. This discolored front advanced behind a still wider area of erythema and induration. There was no crepitus. White blood cell count was 36,000/cu mm with a left shift. x-Ray films showed no abnormal foci of gas production.

The patient was moved to another hospital, observed for 24 hours, and taken to surgery. A circle of periumbilical skin 5 cm in diameter was excised, the dissection being carried down to the rectus sheath. The postoperative course was marked by many complications including seizures (no trismus), bleeding from the operative site, cardiac arrest, and finally, death 36 hours after surgery. Necropsy revealed fibrinoid necrosis of the periumbilical skin. Suppuration and necrosis were found in the umbilicus involving portions of the umbilical vasculature in the abdominal wall. Vessels within the abdominal cavity were not involved. There was no evidence of frank peritonitis, there being only a small focus of fibrin deposition on the peritoneum deep to the operative site. Induration and edema with a sparse inflammatory infiltrate had extended to the dermis and subcutaneous fat of the chest wall and also into retroperitoneal and mediastinal areas. Neuronal degenerative changes were found in the brain. Blood and tissue cultures were negative.

The clostridial species that was also isolated from the mother's vagina was identified as *Clostridium sordelleii.* The species is widely distributed in nature and is rarely pathogenic in man.[1(p220)] *Clostridium sordelleii* produces a β toxin that has a dermonecrotic effect in laboratory animals.[1(pp226-227)]

Comment.—In this fulminating case, the precise role of each of the possible pathogens is difficult to assess, but the findings suggest that exotoxins were a factor. A clostridial organism was cultured from a focus of putrefaction. Well-defined zones of tissue damage were evident clinically and anatomically. Rapid systemic deterioration occurred despite surgery and antibiotic therapy. No evidence of disseminated infection was found.

Clostridial infection and exotoxin elaboration result when contamination occurs under conditions of diminished oxygen tension. These prerequisites can be created by a variety of processes including trauma, natural tissue sloughing (eg, umbilical stump), stasis, and infection. Often other kinds of bacteria help set the stage for clostridial sepsis.[2] Anaerobic infections have been classified into three general categories: superficial with minimal tissue destruction, anaerobic cellulitis, and deep infection with catastrophic events such as gas gangrene, necrotizing myositis, and toxemia.[2(pp406-408),3] The consensus seems to be that the first two categories are easily treated with antibiotic therapy and timely debridement.

It is worth emphasizing that the

presence of clostridia plus putrefaction constitutes almost prima facie evidence that necrotic tissue is present. Such a devitalized focus can serve as an enclave for proliferating bacteria and accumulating toxins. Thus, pathogenic agents lie beyond the reach of blood-borne defenses, drugs, and antitoxins but are quite capable of local extension or systemic dissemination. The kinds of toxins elaborated vary from species to species. Although not all clostridia are regarded as being pathogenic for man, the toxin-producing potential for some organisms is not well known and could vary in unpredictable ways. In light of these facts, much can be said for prompt debridement of tissue that is undergoing putrefaction and digestion, although the timing of surgery is a matter of judgment subject to many variables. Clinicians should be alert for the superficial and cutaneous findings just described that are only rarely seen in modern practice.

Fragmentation of Elastic Fibers

To the Editor.—The June 1976 issue of the ARCHIVES contains an interesting report of a case of acquired cutis laxa.[1] Although we do not doubt the authors' statement that they observed "fragmentation and granulation" of elastic fibers in the skin sections they studied, we submit that Figure 4 of their article does not document that statement.

As we pointed out in 1969,[2] fragmentation of elastic fibers is difficult to prove. Many normal elastic fibers, because of their three-dimensional distribution in the skin, are chopped into short pieces by the microtome knife, and this effect is recognized by the sharp edges of the "fragments" as illustrated in Figure 4 of the article by Scott et al[1] and in Figures 63 and 247 of the second edition of our book.[3] True elastolysis is illustrated in Figure 257 of *A Guide to Dermatohistopathology.*

3. Pinkus H, Mehregan AH: *A Guide to Dermatohistopathology,* ed 2. New York, Appleton-Century-Crofts, 1976.

In Reply.—It has been well acknowledged that fragmentation of elastic fibers is difficult to prove as Dr. Pinkus stated. When we prepared the special stains for elastic fibers, we were keenly aware of this difficulty. Therefore, we compared the preparation of our patient with three other normal specimens.

Even though complete elastolysis was not demonstrated in our patient, we strongly believe that the findings differed significantly from the controls. According to *A Guide to Dermatohistopathology* by Drs Pinkus and Mehregan, it was stated that "The severity of changes varies topographically and some areas of skin may look quite normal."

In addition, the patient died since the publication was submitted, and autopsy material further supported our contention.

Hypothyroidism and Lichen Myxoedematosus

To the Editor.—Case reports and studies to date on lichen myxoedematosus, in particular its rare variant scleromyxoedema of Gottron[1] have stressed the absence clinically and biochemically of associated or complicating hypothyroidism.

Most recently, Hill et al[2] described the successful use of radiation therapy in a patient with lichen myxoedematosus who had laboratory confirmation of normal thyroid function. They propose as one of three criteria for the diagnosis of this condition the exclusion of thyroid dysfunction by clinical and laboratory means. We think this is too restricted a view.

Brigden[3] recently reported a case from our Unit of lichen myxoedematosus in a now 60-year-old man who has been troubled throughout the course of his disease by symptoms attributable to occlusive vascular disease that affect his left internal carotid artery. Increasing lethargy and poverty of thought led to assessment of his thyroid status. Clinical evidence of hypothyroidism was masked by his almost universal cutaneous scleromyxoedema.

Laboratory values from examinations included a serum thyroxine level of 3.0 μg/100 ml (normal range 3.5 to 11.0), a T3 uptake of 88 (normal range 100 ± 20), and a free thyroxine index of 2.6 ng/100 ml (normal range 3 to 13). Thyroid antibodies were not found. The patient's fresh serum was turbid. Lipoprotein electrophoresis revealed raised beta and pre-beta lipoprotein levels. His fasting serum cholesterol level was 338 mg/100 ml; serum triglyceride level was 306 mg/100 ml. These findings were consistent with a type IIB pattern of hyperlipoproteinemia, as defined by Brown.[4] L-thyroxine sodium therapy was commenced; a dramatic improvement in our patient's cerebral symptoms was noted.

It is possible that thyroid dysfunction in this case could have resulted from mucinous infiltration of the gland, as part of a possible systemic mucinosis, but proof would require more detailed investigation. Hypothyroidism thus, may develop with lichen myxoedematosus.[5]

Hill et al,[2] also state that they know of only one case of lichen myxoedematosus, associated with a serum paraproteinemia, having light chains of Kappa type. Our case[3] also is of interest, in that he too demonstrates the characteristic serum IgG paraprotein, having Kappa light chains, making this to our knowledge the second such reported association in the literature.

We wish to state that exclusion of thyroid dysfunction should not be a criterion for the diagnosis of lichen myxoedematosus. Thorough evaluation of thyroid function, perhaps by radiological, histological, and immunofluorescent techniques, should be performed in the continued attempt to elucidate the pathogenesis of this disease.

Familial Lupus: Spectrum of Disease in One Family

To the Editor.—In a recent study on lupus erythematosus (LE), Prystowsky and Gilliam[1] separated their patients into the following three groups: a group of patients with LE limited to the skin; a group with active discoid lesions plus visceral involvement; and a group with proliferative glomerulonephritis. We found this particularly interesting for we were observing at that time a case of familial lupus in which the three probands corresponded to these three distinct groupings.

Report of Cases.—**Case 1.**—A 26-year-old woman was seen in August 1975, with atrophic, tender, hypopigmented areas on her palms and soles, breasts, thighs, and scalp that were accompanied with arthralgia, morning stiffness, recent weight loss, and Raynaud phenomenon. The patient appeared ill and was hospitalized. A test for antinuclear antibody (ANA) was positive in titer of 1:1,280 and was reported as 3+ shaggy. The anti-DNA was less than 1:10 μg/ml. Lupus erythematosus cell preparation was strongly positive. Rheumatoid factor was negative. The C'H50 was 50 units (normal, 25 to 57 units); C3 was 100 mg/100 ml (normal, 125 to 175 mg/100 ml), and the C4 was 28mg/100 ml (normal, 20 to 50 mg/100 ml). Urine reaction for protein was 2+ and the 24-hour urine protein was 735 mg/100 ml. A skin biopsy specimen was taken that was typical of LE. HLA type was 2,9;7,17. The ENA was undetectable. Severe pleuritic chest pain developed during the patient's hospitalization which was diagnosed as lupus pleuritis. She responded to bed rest and salicylate therapy.

Case 2.—This 34-year-old woman, the sister of patient 1, had typical discoid lesions on her scalp, ears, fingers, toes, abdomen, and nostrils, which on biopsy were interpreted as discoid LE. The results of all laboratory studies including the ANA, LE preparation, and complement were either normal or negative. HLA type was 2,9;7,17. The ENA was undetectable.

Case 3.—A 15-year-old female adolescent (another sister) was admitted to the hospital in January 1968, because of a one-week history of generalized edema. Physical examination revealed a cachectic-appearing girl with 1 – 2+ generalized edema. The patient had marked proteinuria and a renal biopsy was performed that demonstrated lupus nephritis. Despite high-dose steroid therapy, her condition steadily deteriorated. Pleural effusion, pneumonia, and renal failure developed and she died in March 1968. An autopsy consent was not obtained, but the laboratory studies shortly before her death revealed the following: hemoglobin level, 6.4 mg/100 ml; urea nitrogen level, 97 mg/100 ml; creatinine clearance, 34 mg/100 ml; 24-hour urine protein level, 6 mg/100 ml; and ANA, 4+. HLA type was not available.

Comment.—Apart from adding another report of familial lupus to the growing literature of familial occurrence of LE,[2] we thought that these cases were interesting because the entire spectrum of LE is demonstrated in one family whereas other familial reports tend to demonstrate a familial systemic or familial discoid lupus.[3-7]

The mother and father were deceased; however, three other siblings were studied extensively. There was no clinical or laboratory evidence of LE. Because of the reported association of HL-A1 and HL-A8[8] with systemic lupus, HLA typing was done on all available family members. HLA types of the involved siblings were already presented. The following types were noted in the uninvolved siblings: HLA type 2,30;14,17; HLA type 2,30;17; and HLA type 2,9;7,17.

Pachyonychia Congenita With Recessive Inheritance

To the Editor.—Pachyonychia congenita (PC), a rare genodermatosis, to our knowledge was first described by Jadassohn and Lewandowsky in 1906.[1] It is characterized by the typically thickened dystrophic nails, keratoderma of the palms and soles, hyperhidrosis, plantar blisters, keratosis pilaris, leukokeratosis oris, ichythosis, steatocytoma multiplex, epidermal cysts, and other features of dyskeratosis such as corneal dystrophy, cataract, hypoplastic hair, and changes in the teeth, nose, ears, and mucous membranes.

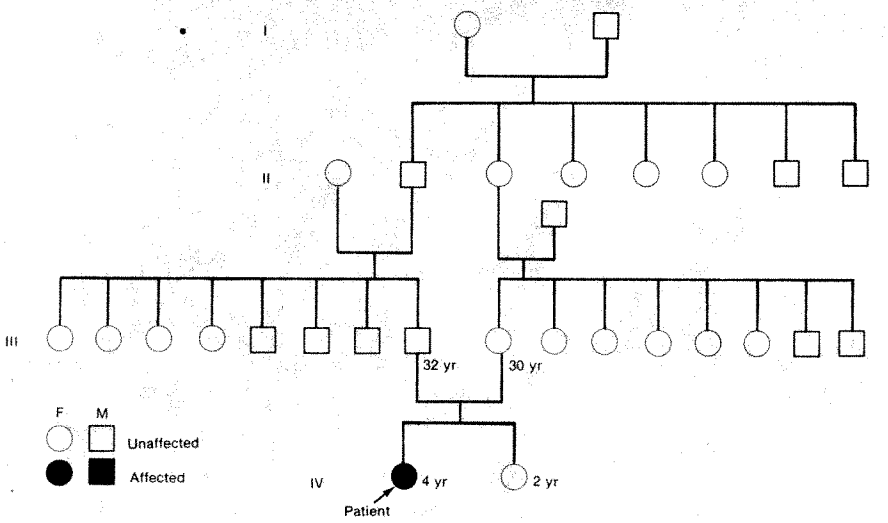
A majority of the cases were reported from Europe and America, and studies from several large families have demonstrated that PC is transmitted as a simple mendelian dominant gene with incomplete penetrance.[2-6]

Asian cases were rarely reported, and the disease, as far as we are aware, has not been known to be inherited as an autosomal recessive trait.

Recently, an Indian girl from Western Malaysia was found to have PC, but the disease appeared to be a recessive disorder, as she was the product of a consanguineous marriage. The inheritance of this interesting patient is briefly discussed.

Report of a Case.—A 4-year-old Indian girl from Johore Bahre, Western Malaysia, was recently seen at our clinic because of her abnormal nails since infancy. Several months after birth, her parents observed that the nails of all her toes and fingers were grossly thickened, distorted, and broke easily at the free edge. Frequent clippings did not prevent this reappearance. The nail beds were readily infected after minor trauma, and occasionally, the whole nail was shed to be replaced by another abnormal nail. She had a transient erythematous rash at the age of 6 months, and was suffering from recurrent "boils" and "dandruff." There was no residual pigmentation or hair loss. Her palms and feet sweated freely, and when she started to walk at approximately one year of age, small blisters and peeling of the skin appeared on the sides of the toes and feet. A year later, small, discrete calluses developed on the sides of the feet and the plantar surface of the toes. About two years ago, her parents noted that small horny lesions developed on both sides of her knees, her elbows, and one buttock. These caused mild irritation and itch. She had no other systemic symptoms. Her birth and milestones were normal and her physical and mental development, too, were normal. Physical examination showed that she was normal for her race, sex, and age. There were no systemic abnormalities, and the significant findings were confined to the nails, skin, and oral mucosa.

Nail Lesions.—All the nails of the



Pedigree, showing autosomal recessive transmission.

fingers and toes were markedly hyperkeratotic, deformed, and dystrophic. The affected nails appeared "pinched up," with narrowing of the lateral nail edges and upward and outward growth of the free edges. Although the nail plate was normally attached to the proximal and lateral grooves, the distal part often protruded beyond the tip of the digits and was considerably raised and arched transversely. Because of the brittleness, the free edges were often jagged and cracked, exposing the piling up of hard keratinous debris from the nail bed under the raised-up nails. Some nails, however, had the appearance of a claw-like incomplete cylinder or cone, eg, the big toes. Subungual keratoses and scars of previous infections were observed in several fingers and toes. On the sides of the toes and feet, peeling of skin from blisters and hyperhidrosis were found.

Skin Lesions.—Besides blisters and skin peeling, the plantar surface of the feet had a number of callosities or keratoderma. These were found on the sites of pressure. Her palms, however, showed mild, diffuse thickening without callus formation. On her knees, elbows, and gluteal surface were numerous follicular keratotic grayish-black papules. The horny cones in the center of these papules fit into the crater-like depressions, and removal of the cones produced points of slight bleeding. On her forehead were five to six small, asymptomatic, soft cystic lesions, and biopsy of one disclosed an epidermal cyst. The patient had no pigmentation, skin atrophy, skin tumors, or other skin lesions on other parts of the body.

Oral Lesion.—A few small patches of white mucosal lesions (leukokeratosis oris) were found in the buccal mucosa, but consent for biopsy was denied. No mucosal lesion was detected in the nose, throat, tongue, or rectum.

Her mental and physical status were normal, and no abnormalities were detected in her eyes, hair, teeth, or other major body organs.

Investigations.—Results of the hematological, urinary, and biochemical tests were all normal. A blood VDRL test was negative. No roentgenological abnormalities were found in the skull and chest. Microscopic examination of the hair did not yield any abnormal findings.

Family Study.—Four generations in this family were examined but none were found to have the features of PC. The family members were all born and bred in Western Malaysia. The patient's father (aged 32) and mother (aged 30) were first cousins. They as well as the patient's younger sister (aged 2) did not show any nail, skin, or other lesions of PC. All of them were well and healthy (Figure).

Comment.—The diagnosis of PC in this Indian girl was established by the clinical picture of the classical dystrophic nails, the presence of hyperhidrosis, plantar blisters, callosities of the soles and palms, keratosis pilaris lesions on the knees, elbows, and one buttock, the epidermal cysts on the forehead, and the leukokeratosis in the buccal mucosa. According to the classification of Kumer and Loos,[2] she belongs to the type II category of PC as she did not have the corneal lesions. Other uncommon associations with this disease but not found in this patient are hypoplastic or kinky hair, natal teeth, microphthalmos, cataract, corneal dystrophy, scrotal tongue, intestinal diverticulosis, and leukoplakia of mucosal membrane.[2-6] The rarity of this disease in Asians is not known. Lack of documentation aside, the nail and skin lesions of PC might often be mislabeled as some common local conditions unless one is aware of the disease and unless a family history is obtained. Most studies in the literature have demonstrated that PC is transmitted as a simple autosomal dominant gene with incomplete penetrance.[2-6]

The disease transmission in our patient is most likely that of the autosomal recessive trait since she was the product of a consanguineous marriage between two first cousins and both of them and the other sibling were unaffected by the disease. The other family members in the four generations too were not affected. However, PC is a very heterogenous disorder, probably involving multiple genes, and hence the possibility of a spontaneous mutation in this family cannot be entirely ruled out.

Erythema Multiforme Resulting From Insecticide Spray

To the Editor.—Recently, we have come across an interesting case, in which erythema multiforme developed in a woman 25 years of age merely a few hours after coming in contact with an insecticide, methyl parathion (Dalf) (2% fanthion), sprayed for killing bedbugs. She had multiple erythematous papulosquamous iris pattern lesions all over her body, with the greatest amount occurring over the extensor aspects of her legs, hands, chest, back, and abdomen that persisted for 20 days. She was not taking any other drugs, had not had a recent vaccination, and had no allergic reactions to food. She did not have a history of similar lesions. All the investigations were within normal limits, except for mild albuminuria and an increase in the eosinophil value. Skin biopsy specimen taken were consistent with the diagnosis of erythema multiforme. She responded well to antiallergic tablets and vitamin C.

Re-exposure to a provocative dose

of methyl parathion insecticide in the form of snuff produced similar lesions. To our knowledge, erythema multiforme produced by inhalations of insecticide, particularly Dalf, has not yet been reported.

Pachyonychia Congenita With Cardiac Involvement

To the Editor.—A case of pachyonychia congenita with cardiac involvement has been recorded and reported. A 9-year-old girl had all the characteristic features of pachyonychia congenita. In addition, there was clinical and roentgenographic evidence of cardiomegaly, with abnormal ECG and angiographic studies. She also had a pigmented nevus in the left iris, spinabifida occulta L5, rudimentary 12th rib, sparse kinky hair over the scalp, and carious teeth.

Report of a case.—A 9-year-old girl born to consanguinous parents was brought to the Dermatology Department on Aug 18, 1974.

When her history was taken, it was noted that approximately three months after birth blisters in frictional areas started to develop. At the age of 7 months, horny follicular lesions mostly over the extremities developed. Nail dystrophy in the form of thickening and lifting up of the nail plates started at the age of 1 year. When the child started walking, blisters developed on the soles and lead to painful peeling off of the skin. At the age of 6 years carious teeth developed as did sparse kinky hair over the scalp. History was suggestive of cyanotic spells with crying that started at the age of 2 years and persisted until the age of 5 years.

On examination she was moderately nourished and slightly anemic. Dermatological examination showed sparse kinky hair over the scalp, keratoderma on the palms and soles, follicular papular lesions over the extremities, verrucous plaques over the elbows, knees, and gluteal folds, large ruptured bullae with exfoliation in both soles, and leukokeratosis in the buccal mucosa. All the nail plates were thickened with subungual hyperkeratosis and lifting up of the nail plates distally. Systemic examination showed clinical and roentgenographic evidence of cardiomegaly; the pulmonic second sound was loud and split; her pulse rate was 108 beats per minute; and blood pressure was 100/80 mm Hg.

Fluoroscopy revealed cardiomegaly. The C/T ratio was 60:40. Visible pulsations and minimal enlargement of both ventricular chambers were present. Electrocardiogram showed normal sinus rhythm, left anterior fascicular block, and nondiagnostic T wave changes anterolaterally. Though mere T wave with S-T segment changes can happen in any primary myocardial disease, the Q-S pattern in V_2 and V_3 was more in favor of a specific anamolous origin of coronary artery from pulmonary artery.

The angiography report by Dr T.J. Cherian was as follows:

> Catheter in the pulmonary artery in the AP view shows normal pulmonary artery and its branches and on recirculation the left atrium and left ventricle opacified normally. The left ventricular contraction appears to be sluggish but there was no evidence of thinning of the ventricular musculature. Aortic root injection in AP view shows both right and left coronary arteries filling normally and the right coronary artery appears to be the dominant artery. The left ventricular injection in the RAO shows a dilated left ventricle with a number of premature ventricular contractions but in the later phase ventricular contractions appear to be sluggish. The overall impression was suggestive of myocarditis.

Correction of the anemia did not improve her cardiac condition.

Comment.—This case had all the characteristic features of pachyonychia congenita as described in the literature. In addition, this case had a cardiac abnormality along with an abnormality of the left iris that to our knowledge have not been reported in the literature so far. It is worthwhile in the future to look for a cardiac abnormality in cases of pachyonychia congenita to decide whether this association we have reported is merely fortuitous or whether a cardiac anamoly might also occur in a full-fledged case of pachyonychia congenita.

S. Premalatha, MD, DD
A. S. Thambiah, FRCP, FAMS
Madras, India

Dr T. J. Cherian, physician, did the investigations and the report on the cardiac condition.

Toxic Epidermal Necrolysis in a Patient With Ovarian Carcinoma

To the Editor.—Toxic epidermal necrolysis is recognized with increasing frequency in association with an enlarging variety of other diseases and is apparently precipitated by a very wide spectrum of triggering mechanisms. Rarer but important associations have also been reported and we would like to report another example in this category of toxic epidermal necrolysis occurring in association with a systemic neoplasm.

Report of a Case.—A 66-year-old housewife had a hysterectomy for fibroids 16 years previously and had been active and well until recently when indigestion and water brash developed and she began to lose weight. Her epigastric pain was related to eating food and the pain radiated to the back and was adequately relieved by antacids. On examination, the only abnormal physical sign was an aortic systolic (grade 2) murmur.

Laboratory studies on admission revealed an ESR of 104 mm/hr, a hemoglobin value 11.4 gm/100 ml, an erythrocyte count of 3.8×10^6/liter, and a leukocyte count of 6,000/cu mm with normal differential distribution. The plasma urea value was 84 mg/100 ml. Plasma potassium was persistently low at a value of 2.8 mEq/liter. Liver function test results showed strongly positive thymol flocculation and thymol turbidity at 9 MacLagen units. The urinary protein level was 30 mg/liter of urine. No Bence-Jones protein was detected. Immunoglobin IgA and IgM values were normal, but the IgG level was raised at 21.40 gm/liter. Other investigations reported to be normal were x-ray films of the chest and abdomen, barium meal examination of the esophagus, stomach, and duodenum and findings from biopsy of the liver and biopsy of the temporal artery. Results from the bacteriological examination of the skin, nose, mouth, and sputum were all reported to be normal apart from the usual commensals. There were no lupus erythematosus cells in the blood and results from immunofluorescent tests for antinuclear, mitochondrial, and smooth muscle antibodies were all normal. Her protein-bound iodine value was within normal range at 5.6 μg/100 ml.

The patient continued to receive antacids and was about to be discharged home to await a lymphangiogram when an itchy vesicular eruption rapidly developed on the legs and trunk. Swabs taken from these sites for bacteriological culture were reported negative for *Staphylococcus aureus* and other pathogenic organisms. After several days, the skin rash developed into a blistering skin eruption that showed grouped tense clear vesicles on erythematous bases scattered over the trunk and elbows.

A provisional diagnosis of bullous pemphigoid or dermatitis herpetiformis was made at this time. A biopsy specimen was taken for histological examination and serum for immunofluorescence tests. Dapsone 50 mg twice daily was prescribed. Six days later, however, the patient's condition rapidly deteriorated. In the words of her own physician, "Her skin had come off overnight" and she was found to have the characteristic eruption of toxic epidermal necrolysis. The trunk and limbs were covered with widespread areas of erythema on which were scattered clear vesicles and bullae. Certain denuded friction sites looked like severe scalds. The patient was given prednisolone phosphate 60 mg daily and during the first week of this treatment

the skin eruption improved, fresh blisters ceased to appear, and erosions began to heal. Unfortunately, this remission was a brief one. Her hemoglobin level was found to have decreased to 7.4 gm/100 ml and the blood film showed a leuko-erythroblastic picture with lymphopenia, and marked toxic granulation of neutrophils. The erythrocyte sedimentation rate was 53 mm in one hour. Her blood urea level rose to 119 mg/100 ml.

Histological section of the blister biopsy specimen reported the following; a subepidermal bulla in which there were eosinophils, there was no acantholysis, and vasculitis was not a feature. Immunofluorescent staining of the skin biopsy specimen revealed IgG fixation along the basement membrane and considerable excess of IgG-producing cells in the dermis. Immunofluorescent tests for antibody to skin basement membrane were positive but negative to skin desmosomes.

After four weeks, she died and at necropsy the left ovary was found to be replaced by a neoplasm 5 cm in diameter. Secondary deposits were found in the para-aortic lymph nodes. Histological examination of the ovarian and para-aortic metastases confirmed a papillary carcinoma.

Comment.—An association of malignant neoplasia with vesico-bullous skin eruptions has been alleged since 1909 when a dermatitis herpitiformis-like rash appeared on a 28-year-old woman who was found two months later to have carcinoma of the labium.[1] However, a recent retrospective survey of patients who attended the Mayo Clinic failed to find any significant association between systemic malignant disease and bullous skin eruptions. The case reported here, therefore, may be no more than a rare coincidental pathological relation between an ovarian tumor and toxic epidermal necrolysis. The provocative role of dapsone cannot be excluded particularly in view of its known association with toxic epidermal necrosis.[2] The significance of this case lies in the peculiar change of form of the skin eruption. For example, an itchy erythematous rash is certainly a remarkable antecedent for toxic epidermal necrosis, whereas the late dramatic dermatological changes were more characteristic. Transitional stages of pemphigus into toxic epidermal necrosis have previously been described without the presence of a tumor.[3]

Thymus Lymphocytes of the Peripheral Blood in Patients With Alopecia Areata

To the Editor.—Previous authors have reported depression of peripheral thymus lymphocytes (T-cells) in atopic dermatitis.[1,2] Atopic dermatitis is frequently associated with another autoimmune disease, alopecia areata (AA).[3] We evaluated T-cell levels in 60 patients with AA who were between the ages of 2 and 52 years. T-cell levels in AA were compared to 51 normal controls.[4] The mean percentage of T-lymphocytes in AA was 58.9% compared with the normal control population of 74.9%. The T-cell number per cubic millimeter was 1,184 in subjects with AA, compared with the normal control of 1,461/cu mm (Table 1). The T-cell percentage and T-cell number of AA was significantly different from the controls at $P < .001$. A total of 97% of our patients with AA had depressed T-cells in the peripheral blood (Table 2). A total of 58% of the patients with AA had less than 1,200 T-cells per cubic millimeter of peripheral blood (Table 3).

Autoimmune-type endocrine diseases and autoantibodies in AA have been previously reported.[5] Depressed T-cells would also support an autoimmune process responsible for AA rather than attributing the disease process strictly to psychic stress. Further studies are in progress to correlate the levels of T-lymphocytes with other tests of immune competence, different stages of AA, ie, AA totalis and universalis, and the age of onset. These studies will indicate the usefulness of the T-cell assay in the diagnosis and prognosis of alopecia areata. Our study should stimulate the physician to consider an autoimmune origin and endocrine disease in AA.

Hypopigmentation With Punctate Keratosis of the Palms and Soles

To the Editor.—I read with interest the article entitled "Hypopigmentation with Punctate Keratosis of the Palms and Soles," by Maj Lonnie A. Cole, MC, USAF, that appeared in the July 1976 issue of the ARCHIVES (112:998-1000).

In connection with that case report, I should like to advert to an article entitled "Hereditary Sclerosing Poikiloderma" by Weary PE et al, that appeared in the October 1969 issue of the ARCHIVES (100:413-422) and that described several patients bearing striking resemblance to those reported by Dr Cole.

Although apparently differing in several respects, there seems to be sufficient clinical similarity between the patients comprising the two series to warrant critical comparison.

SAMUEL B. PRATT, MD
TOMMY B. GRIFFIN, MD
GEORGE S. STRETCHER, MD
Spartanburg, SC

In Reply.—I am indebted to Dr Pratt for pointing out to me the considerable visual similarities of my patient and those reported by Weary et al (ARCHIVES 100:413-422, 1969). In fact, the dyschromia present in any of the various poikilodermas shows some resemblance to that of my patient. However, the findings of atrophy, telangiectasia, and hyperpigmentation were completely lacking in my patient. In addition, Dr Weary's patients had sclerotic bands in their flexural areas that were absent in the patient I reported. My patient did not have more extensive involvement of the elbows and knees, clubbing of the fingers, or calcinosis cutis. Finally, the diffuse sclerotic changes in the palms and soles of Dr Weary's patients differed from the punctate keratoses of my patient. Despite the similarities, I believe there are enough differences to establish these cases as two separate entities.

Tampa, Fla

Iatrogenic Traumatic Purpura Masquerading as Vasculitis

To the Editor.—Palpable purpura suggests a number of disease states including necrotizing vasculitis, drug eruption, purpura fulminans, insect bite, and the progressive pigmented dermatoses. Histologically, an inflammatory infiltrate that is made up of either polymorphonuclear leukocytes or lymphocytes is often seen in a perivascular distribution. The following cases point out a further cause of palpable purpura that should be of particular interest to the hospital-based dermatologist.

Report of Cases.—Case 1.—A 76-year-old man was brought to the emergency room complaining of the abrupt onset of left-sided weakness, accompanied by stool and urine incontinence. The patient was admitted. In-hospital physical examination demonstrated an elderly, alert man with mild hypertension and left-sided hemiparesis. In addition, there were multiple, slightly palpable, well-demarcated, grouped, violaceous, nonblanching, 0.5 × 0.5-cm lesions, with a central area of hemorrhage over both lower extremities; they were more frequent on the paretic extremity. The lesions were present over the dorsa and the soles of the feet, extending to the thighs. There was an area on the left thigh where the lesions appeared in a linear distribution. There were similar purpuric lesions over the posterior upper arms bilaterally. Nonblanching erythema of the palms and soles was also noted.

Laboratory findings showed normal clotting studies. Lumbar puncture demonstrated many RBCs, and no WBCs. Lupus erythematosus preparation, antinuclear factor, and VDRL test were negative. A skin biopsy of one of the lesions showed dermal hemorrhage without evidence of vasculitis.

Further history revealed that on admission to the emergency room the sensory portion of the neurologic examination was performed with a hollow-bore needle. The initial examination was concentrated on the paretic side of the body and the lesions could be subsequently duplicated by performing the sensory examination with a No. 18- to No. 26-gauge needle. The patient's lesions gradually resolved without treatment.

Case 2.—A 31-year-old man came as an outpatient to the Dermatology Section with a two-day history of an asymptomatic eruption primarily over the left side of the body. He had noted mild paresis of the left upper and lower extremities for several months and had been evaluated in the Orthopedics Section several days earlier.

The physical examination showed multiple, 3- to 6-mm, grouped, erythematous, nonblanching, slightly palpable lesions primarily over the left side of the body. Each lesion had a hemorrhagic center. Mild weakness of the left upper and lower extremities was noted. Laboratory findings including clotting studies were within normal limits. Additional history revealed that the neurologic examination had been performed with a hollow-bore needle at the time of the previous evaluation. Subsequently, the lesions were reproduced with No. 20- and No. 26-gauge needles.

The causes of purpura are usually classified according to extravascular, vascular, or intravascular etiologies. Among the vascular etiologies, traumatic purpura is included.[1] The essentials for diagnosis include a normal hematologic workup and a history of trauma directly to the area of involvement. We are reporting a characteristic type of acquired vascular purpura, ie, traumatic purpura secondary to neurologic examination performed with a hollow-bore needle. It is important to distinguish these hemorrhagic lesions from those of necrotizing vasculitis wih CNS involvement. Both of our patients came to the dermatologist after evaluation for a neurologic deficit. Both had a grouped, or even linear distribution of their lesions, and more were noted on the affected side. In both patients, the lesions were asymptomatic and were able to be reproduced by performing the sensory portion of the neurologic examination with a hollow-bore needle. Similar lesions were produced in normal controls. The lesions uniformly resolved in five to seven days without treatment.

**Final cure rate comparing haloprogin and tolnaftate therapy.

Pre-Treatment | After 4 Weeks of Treatment | After 6 Weeks of Treatment

Halotex has been proven in other tineas; tinea cruris, tinea corporis, tinea manuum, and tinea versicolor.

tinea in its tracks, with one Rx.

Consider the many benefits of Halotex when you next write for a topical antifungal agent.

- **Effective: Proven against most common tinea pathogens.**
- **Proven: In 1,062 patients, only 29 reported either itching or burning associated with application.[2]**
- **Economical: Priced with patient economy in mind.**

Halotex provides controlled therapy, Rx only. It is available in both liquid and cream forms packaged in 30 g tubes for cream and in 30 ml bottles of liquid . . . adequate dosage for full treatment periods. A 10 ml bottle of liquid is available for small areas. It is a single entity product, nongreasy, nonstaining.

Halotex® (haloprogin)

1% Cream/Solution

One Rx is usually enough.

Halotex®
(haloprogin)
1% Cream/Solution
Caution: Federal law prohibits dispensing without prescription.

Description: Halotex cream provides 1% haloprogin in a water-dispersible, semi-solid cream base. Each gram contains 10 mg. haloprogin solubilized in polyethylene glycol 400, polyethylene glycol 4000, diethyl sebacate and polyvinylpyrrolidone. Halotex solution provides 1% (10 mg. per ml.) haloprogin in a homogeneous vehicle of diethyl sebacate and alcohol.

Action: Halotex is a synthetic antifungal agent for the treatment of superficial fungal infections of the skin.

Indications: Halotex cream and solution are indicated for the topical treatment of tinea pedis, tinea cruris, tinea corporis and tinea manuum due to infection with Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Microsporum canis, and Epidermophyton floccosum. It is also useful in the topical treatment of tinea versicolor due to Malassezia furfur.

Contraindications: Halotex preparations are contraindicated in those individuals who have shown hypersensitivity to any of the components.

Warning: USAGE IN PREGNANCY—Safety for use in pregnancy has not been established.

Precautions: In case of sensitization or irritation due to Halotex cream or solution or any of the ingredients, treatment with these preparations should be discontinued and appropriate therapy instituted.

If a patient shows no improvement after four weeks of treatment with Halotex cream or solution, the diagnosis should be redetermined. In mixed infections where bacteria or nonsusceptible fungi are present, supplementary systemic anti-infective therapy may be indicated.

For external use only. KEEP OUT OF EYES.

Adverse Reactions: Reactions reported include: (1) local irritation, burning sensation, vesicle formation, and (2) increased maceration, pruritus or exacerbation of pre-existing lesions.

Dosage and Administration: Halotex cream and solution should be applied liberally to the affected area twice daily for two to three weeks. Interdigital lesions may require up to four weeks of therapy.

How Supplied: Halotex® cream 1% (10 mg. per g.) 30 g. collapsible aluminum tube NDC 0072-7130-02.

Halotex® solution 1% (10 mg. per ml.) 10 ml. polyethylene bottle with controlled drop tip NDC 0072-7210-02 and 30 ml. polyethylene bottle with controlled drop tip NDC 0072-7230-02.

David F. Fretzin, MD, Recorder

Prurigo Nodularis. Presented by DAVID F. FRETZIN, MD.

A 56-year-old woman has a three-year history of a persistent pruritic eruption involving most areas of her body except the head, neck, and the anterior part of her chest. She has severe episodic pruritus at which time she scratches lesions until they excoriate and bleed. Individual lesions may gradually recede, leaving hyperpigmented macules. Pruritus seems worse in the spring "grass season" and with stress. In 1972, a clinical diagnosis of Mucha-Habermann's syndrome was suggested elsewhere, but a biopsy specimen showed only chronic psoriasiform dermatitis. Treatment in the past had consisted of long-term high doses of tetracycline, systemic corticosteroids, tranquilizers, diuretics, thyroid pills, and a variety of topical remedies, including steroid preparations. She has a past history of hay fever as a girl and sinusitis since that time. She also has occasional episodes of eczematous eruptions on her hands, legs, feet, and ears. There is a questionable history of decreased thyroid activity.

Results of physical examination show numerous discrete, firm, uniform, shiny to hyperpigmented nodules scattered evenly on portions of her trunk, arms, and legs (Figure). Some are excoriated and crusted. A scaling hyperpigmented chronic eczematous eruption is present on her ankles. A biopsy specimen of a nodular lesion shows focal hyperkeratosis and parakeratosis, as well as notable pseudoepitheliomatous hyperplasia. The papillary and upper dermis is highly vascular and associated with a primarily chronic, but focal, inflammatory reaction. Some fibrosis is present. There is exocytosis of inflammatory cells. No distinct hyperplastic nerve bundles are noted.

Discussion

DR FREDERICK MALKINSON: The only temporary success I have had has been with the use of tar preparations locally. Topical steroids are often ineffective. In some patients, the lesions are almost impossible to eradicate short of surgical removal. I have seen one patient in whom some of the nodules were excised.

DR RICHARD WINKELMANN: Do you have any comments about the relationship to atopy?

DR MALKINSON: I have seen few cases, perhaps one every year or two. I have not been impressed that most occur in patients with atopy.

DR. WINKELMANN: This patient had hay fever and has a daughter with hay fever and a niece with severe atopic dermatitis, so this is a factor to be considered. Some of the patients we have seen with prurigo nodularis have had high IgE values. Patients with prurigo nodularis have a tendency to itch based on the pharmacology, physiology, and/or immunologic and perhaps IgE reactivity of their skin.

DR WILLIAM CARO: The histology is characteristic and yet not very specific. It shows essentially a hyperplastic epithelium with irregular acanthosis with maturing keratinocytes. In the dermis is a nonspecific inflammatory infiltrate of lymphocytes and histiocytes. About ten years ago, there was some discussion in the literature by a British dermatologist on the finding of hyperplastic nerve endings in the upper portion of the dermis. He believed that this might have something to do with the extreme itching that these patients experience. I have had an opportunity to look at four or five of these cases since then and have not identified abnormal, large nerve endings. The picture is a nonspecific one, and some of these both clinically and histologically start to merge with multiple keratoacanthomas.

DR DAVID FRETZIN: Serial sections were obtained on a biopsy specimen of a lesion, and we were unable to find any large nerve bundles. The interesting thing is that most

Multiple discrete prurigo nodules on arms of patient.

textbooks report that the itching is episodic and occurs only on the lesion. However, our patient complains that she itches in areas where she does not have lesions. I am not sure whether this relates to an atopic tendency, since at times she has eczematous patches, which are obviously different from the prurigo nodularis that we see here.

DR LAWRENCE SOLOMON: Dr Winkelmann's suggestion that IgE is related to atopic dermatitis might lead one to the erroneous conclusion that IgE causes atopic dermatitis. I think the evidence is accumulating rather rapidly and convincingly that IgE may be considered as the crowd that gathers at the accident; it is not necessarily the cause of the accident (ie, dermatitis). There are patients with atopic dermatitis who do not have raised IgE levels, and there are patients with high IgE levels who do not have atopic dermatitis. There is also convincing evidence that patients with atopic dermatitis are T-cell deficient. It is entirely possible that the purpose of increased IgE levels in patients with atopic dermatitis is simply an attempt by the organism to make up for a T-cell deficiency by stimulating B cells, where such stimulation has been initiated by an appropriate antigen.

Chronic Mucocutaneous Candidiasis, Vitiligo, Polyendocrinopathy, Pernicious Anemia: Subacute Combined Degeneration of the Spinal Cord. Presented by RUTH K. FREINKEL, MD and MICHAEL S. ASHMAN, MD.

This 34-year-old woman is being followed up for multiple endocrine and cutaneous problems. At age 4 years, the patient's diarrhea, photophobia, and growth retardation were diagnosed as attributable to idiopathic hypoparathyroidism. At age 6 years, she developed moniliasis affecting the hands, nails, mouth, and vagina, which has persisted. The patient was unavailable for follow-up, while episodes of tetany and progressive loss of vision occurred. Treatment with oral calcium and vitamin D was instituted at 12 years of age. A macrocytic anemia was detected and was treated with folic acid. Progressive neurologic symptoms compatible with subacute degeneration of the spinal cord developed at age 15 years. At age 18 years, pernicious anemia was diagnosed, and vitamin B_{12} therapy was begun. Menarche occurred at age 15, and menses ceased at 22 years of age. Decreased estrogen effect on vaginal smear was detected at this time. At age 17 years, there was sudden onset of total scalp alopecia that progressed to alopecia universalis. By age 24 years, she had extensive vitiligo. In 1971, she was examined for muscle weakness and muscle spasm, diarrhea, and parathesias in the hands. An intensive examination showed hypoparathyroidism, partial blindness with corneal vascularization and lenticular opacities, and cutaneous moniliasis. Thyroid and adrenal function were normal. No serum thyroid antibodies were detected.

She responded to treatment with intravenously administered calcium and steroids. Steroid dosage was decreased, and treatment with vitamins D and B_{12}, oral calcium, and cyclic Enovid E was maintained. Her cutaneous moniliasis continued to worsen, and she was readmitted for evaluation of her endocrine and immunologic status. Moniliasis now involved her hands, nails, tongue, and lips. While she had normal baseline cortisol levels, her adrenal reserve was diminished, as shown by a three-day adrenocorticotropic hormone stimulation test. Primary ovarian hypofunction was demonstrated by diminished urine estrogens and high urinary gonadotropins. Pituitary gland growth hormone assay was normal by insulin stress. The patient had a positive skin test to mumps antigen and was negative for *Candida*, *Trichophyton*, and purified protein derivative intermediate. Previous therapy was continued, and it was elected not to treat her skin condition. She has had a left corneal transplant, with improvement of vision. Her two brothers, mother, and father are in excellent health.

On examination, her blood pressure was 117/80 mm Hg, and her pulse rate was 78 beats per minute. She appears alert and intelligent. There is total body alopecia; her finger and toe nails are gray, dystrophic, irregularly formed, and crumbling. Vitiligo is noted around her eyes and mouth and at pressure points on her elbows, knees, hands, and fingers. There are confluent, round, erythematous, and scaling plaques on her wrist, fingers, and feet. Her right cornea is opaque, and her left cornea has a transplant. The pupils react poorly to light and in accommodation. The retina is not visualized. Her throat shows typical moniliasis, and her teeth are pointed, malformed, and brown-stained. There is gross motor weakness in her legs; the patellar reflexes are brisk, and her toes are upgoing. She has normal sensation and no Chvostek sign.

Her hemogram, serum calcium, serum phosphorus, and serum electrolyte levels; and urinalysis are normal. A chest roentgenogram is normal. A culture of scales from the dorsum of the hand grew *Candida albicans*. Her 24-hour urine excretion of 17-ketosteroids was 5.8 mg/24 hr (normal, 5 to 15 mg), and her 17-hydroxycorticosteroids excretion was 2.6 mg/24 hr (normal, 3 to 8 mg). A 24-hour urine for free cortisol was reported as 40.2 μg (normal, 20 to 100 μg). At present the patient has normal thyroid function and reserve, and normal thyroid-stimulating hormone levels. Direct and indirect immunofluorescence studies were negative for immunoglobulin and complement in her skin. Skin testing with four standard antigens was negative (*Candida*, mumps, *Trichophyton*, and streptokinase-streptodornase). The patient's lymphocytes responded normally to pokeweed mitogen and phytohemagglutinin antigen stimulation. When cultured in 20% autologous plasma, the patient's lymphocyte response to both pokeweed mitogen and phytohemagglutinin antigen stimulation was diminished, indicating the presence of circulating lymphocyte inhibitors. However, her serum did not inhibit normal lymphocytes. *Candida* antigen also could not include patient lymphocyte response in both autologous and normal allogeneic plasma. The patient's peripheral blood T- and B-lymphocyte percentages were within normal limits. The IgD-bearing B-lymphocytes were increased ten times the normal number, for reasons that are unclear. Her treatment consists of vitamin D (100,000 and 50,000 units on alternate days), Enovid E, one glass of milk a day, and vitamin B_{12} (0.1 ml intramuscularly administered every week).

Discussion

DR ALVIN ZELICKSON: It is not unusual to see immunologic problems associated with vitiligo. We have been studying these patients and trying to come up with a morphologic definition of vitiligo. It would be interesting to see if she has an increase in Langerhans cells. We have studied several cases with immunologic disorders, especially one family with an IgE problem, and in those cases we found no Langerhans cells and no melanocytes. This woman fits into the class of what I would call leukodermas that need more evaluation.

DR RICHARD WINKELMANN: I was interested that her delayed hypersensitivity tests presently seem to be normal.

DR RUTH FREINKEL: Her cutaneous sensitivity is not entirely normal since she is negative to *Candida*. Ratios of B cells and T cells are normal. However, there is a group of patients with chronic moniliasis who respond normally to the usual sort of mitogens, suggesting that their T cells have some normal receptor sites but will not respond with mitogenic activity to *Candida*. In addition to that, her serum inhibits the response of her lymphocytes to phytohemagglutinin, but does not inhibit the response of normal lymphocytes. We have not seen this patient without skin disease, since she refuses systemic treatment. Presently, we do not know if inhibition of mitogenic stimulation is related to activity of the disease. I would like to ask Dr Zelickson if this is not vitiligo in the ordinary sense of the word. Why do patients with these types of endocrine disorders and pernicious anemia develop leukoderma?

DR ZELICKSON: At our institution, Dr Katz reported a series of cases associating pernicious anemia with vitiligo. The question he was concerned with is: If someone has vitiligo is he predisposed to these other

problems? The question I ask is how do we know this is vitiligo? Some believe that anyone who has gray hair has vitiligo. There will be a certain group that has a definite relationship to immunologic problems and others that have no relationship whatsoever. Also some of these patients tend to repigment well with the psoralens, whereas others do not.

DR WINKELMANN: What I find confusing about this group of interesting polyendocrinopathies with candidiasis is that they can occur at various ages, but they all seem to be related to delayed hypersensitivity dysfunction. There are half a dozen cases in the literature where erythroderma and lack of thymus function is apparently the reason for *Candida* overgrowth, and this patient seems to be at the other end, where the polyendocrinopathies occurred from either some congenital problem like the Sipple syndrome or from some kind of inflammatory attack on the organs.

DR H. BURSTEIN: This patient shows impaired cellular immunity and cutaneous anergy as seen in chronic mucocutaneous candidiasis, thymoma, and myopathy. The four cases of this triad reported to date were also women, but were more than 50 years of age when cutaneous lesions developed. Thymectomy was performed 14 years ago on my patient, but her candidiasis has persisted. In a recent letter, she mentioned improvement of her skin the past year after treatment with intensive oral vitamin E in addition to multivitamin tablets.

DAVID F. FRETZIN, MD, Recorder

Pustular Psoriasis in a Child. Presented by MARSHALL BLANKENSHIP, MD.

A 2½-year-old boy was born in May 1972 after a normal pregnancy and delivery. The mother was taking a diuretic three weeks prior to delivery. There was mild jaundice and hyperbilirubinemia 12 hours after birth that was most likely due to polycythemia. He received ultraviolet light treatments, and the jaundice cleared within one week. Within the first month of life, he developed erythema and scaling on his neck and diaper area. The eruption became generalized and has continued with short remissions and exacerbations. At times there are severe acute flares with superficial pustules and a febrile state. There has always been dystrophy of the nails. He has failed to gain weight, but pediatric examinations have found no evidence of any other disease process. He has not had diarrhea or other gastrointestinal symptoms. Results of a biopsy elsewhere were consistent with psoriasis. Topical steroids have produced symptomatic improvement but have not altered the clinical course. Oral antibiotics have no definite effect. Our biopsy was consistent with psoriasis.

Discussion

HAROLD PERRY, MD: Small discrete pustules clustered in serpiginous erythematous plaques are present on the palms, and less distinctly over the trunk. The biopsy specimen showed the pustular reaction of Kogoj that I associate with pustular psoriasis. This child is quite young to have pustular psoriasis of Zumbusch. There are any number of insults that tend to aggravate the disease. Streptococcal infections, superimposed contact reactions, sun exposure, and trauma to the skin in some way precipitate an exaggerated pustular reaction. The presence of recurrent fever in patients with pustular psoriasis and the alteration of the calcium levels are things one must evaluate. Pustular psoriasis is a cyclical disease; there will be exacerbations but there will also be remissions. I would treat this child gently with topical steroid creams and wet dressings as required; perhaps some tar and light (the Goeckerman program). Severely toxic chemotherapeutic agents should generally be avoided. I would avoid methotrexate in a child of this age. Under most circumstances, the cutaneous reaction eventually will wane following topical treatment. The child will be able to live with this disease. A major problem is to omit any treatment that will precipitate irreversible physiologic changes.

ALLEN LORINCZ, MD: Occasionally a patient with pustular psoriasis responds to sulfapyridine or sulfone therapy. This might be worthwhile, particularly if the systemic illness is life threatening.

WILLIAMS CARO, MD: Both the histopathologic and the clinical pictures are good for pustular psoriasis. I did not see in the protocol whether the investigators had checked for the possibility of candidal infection. Some of the lesions were somewhat circinate in configuration, with heaped up, almost rupial appearance. Although such a lesion can appear in psoriasis, it also can be a hallmark of an early candidal granuloma. Testing for candidal infection with cultures and a PAS stain on the biopsy might give additional information.

WILLIAM RUSSELL, MD: There is support for the concept of streptococci as etiologic factors in some cases of psoriasis. Antistreptolysin titers have been significantly elevated in psoriatic patient populations. This has been interpreted as indicating possible increased susceptibility to streptococcal infections in HL-A13 patients.[1] Clinically, evidence has been presented implicating a relationship of HL-A13 psoriatic patients with antecedent streptococcal infections.[2] Tissue typing may be of value in this patient. I would also be aggressive with serial antistreptolysin O and streptozyme titers, as well as repeated throat cultures for upper respiratory infections. Resumption of prophylactic antibiotic therapy is also a consideration.

ADOLPH ROSTENBERG, MD: What are you going to do with this boy in a few years when he becomes of school age? Dr Rothman used to say "psoriasis does not destroy life, it merely ruins it." It's easy to be complacent and treat patients on the safe side because you sleep better that way, but you may not be making the best decision for the patient. If this boy were of school age, or older, one would have to be more aggressive. You have to take chances so that this child may lead a more or less normal life.

RICHARD WINKELMANN, MD: An article in the ARCHIVES in 1974 summarized the cases of 47 children with pustular psoriasis. The authors pointed out that this annular form has a recurrent course and a better prognosis, and I hope that this patient will fall into the category of their favorable cases and not require the intensive therapy that might be proposed. We've used tar in massive amounts in many patients with psoriasis almost on a yearly basis for many years, and we have never seen a substantial problem.

MARSHALL BLANKENSHIP, MD: The clinical course has been one of exacerbations and remissions, and thus far the treatments have not shortened or prevented the flares. The patient was placed on sulfapyridine at the Mayo Clinic, and there was no change. His condition exacerbated at one time with topical tars, and the mother will not use tars again. Dr Gerald Weinstein agreed that methotrexate was not indicated at present. When he has acute exacerbations, he often has a fever, but I cannot determine whether he has had an infection that causes the pustules and erythema or whether the acute changes produce the febrile state. Antibiotics given prophylactically have never changed the course, shortened the flares, or reduced the fever. He does much better in the summer. I will try ultraviolet-light therapy alone initially, and then maybe I can slowly get his mother to accept the use of a mild tar preparation.

Familial Macular Amyloidosis Masquerading as Incontinentia Pigmenti. Presented by ANA M. ENG, MD.

A 41-year-old man was admitted for evaluation of his cardiopulmonary status because of progressive shortness of breath. Pulmonary stenosis with cardiomegaly was diagnosed in 1963. He has had diabetes mellitus since 1957, controlled with 40 units of isophane insulin suspension. An asymptomatic, generalized hyperpigmentation on his trunk has been present since childhood, not preceded by blisters or verrucous changes. Two sisters, two brothers, and a paternal uncle have diabetes mellitus. One

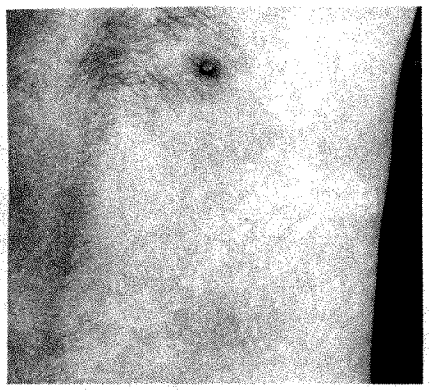

Fig 1.—Swirling pattern of hyperpigmentation and hypopigmentation on left flank.

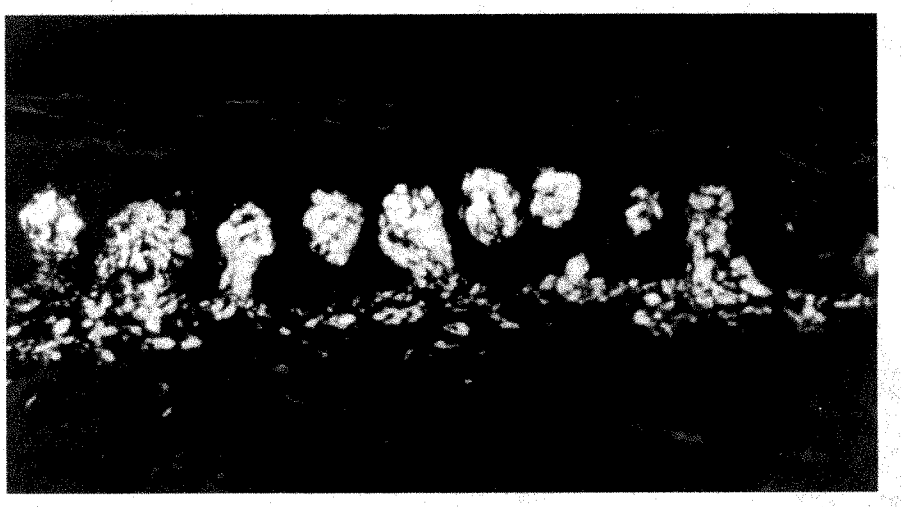

Fig 2.—Thioflavin T preparation with polarization demonstrating amyloid in papillary dermis.

of the sisters has similar skin manifestations, diabetes, and cardiomegaly of unknown cause. The daughter of this sister has been deaf since birth.

Physical examination results showed a systolic murmur at the second intercostal space. His skin showed generalized hyperpigmentation with hypopigmented 2- to 5-mm macules on the trunk. Hypopigmented whorls and swirls were present on the left lateral trunk. Biochemical screening tests were normal except for an LDH of 300 IU/liter. Chest x-ray film revealed a reticulonodular pattern suggestive of chronic fibrosis. Results of pulmonary function tests suggested alveolar-capillary block. An electrocardiogram showed sinus bradycardia, right ventricular hypertrophy, and right atrial enlargement. On cardiac catherization, there was evidence of moderate pulmonic valvular stenosis and normal left and right ventricular function. A lung biopsy demonstrated interstitial fibrosis with a suggestion of amyloidosis. Skin biopsy specimens from the patient's hyperpigmented areas showed amyloid in the papillary dermis with increased melanin in the epidermal cells. Biopsy specimens from hypopigmented spots on his left trunk and back showed amyloid in the papillary dermis with melanin incontinence. Skin biopsy specimens from the sister also revealed amyloid in the papillary dermis. The patient's pulmonary status was improved on a regimen of 30 mg of prednisone a day.

BERNARD ACKERMAN, MD: When I saw this patient, I did not think instinctively of macular amyloidosis. I saw the hematoxylin-eosin-stained slide very briefly. The one glance that I had of this case of apparent macular amyloidosis showed homogeneous eosinophilic material in the papillary dermis, but one has to be careful about making a diagnosis in difficult cases such as this without confirmation by special stains such as crystal violet, Congo red, or polarization of thioflavin T. I think that lichenoid amyloidosis is simply macular amyloidosis with superimposed lichen simplex chronicus.

DR WINKELMANN: As I read through this protocol, I did not see any evidence of staining for iron or effort to look at the liver function. Here is a young patient with diabetes and pigmentation, and I think we should look aggressively rather than passively. I would agree that a possibility of some secondary degenerative change like amyloid in the skin might exist. What is the evidence that the family has amyloid?

DR ANA ENG: My initial impression was that of a pigmentary disorder. I agree that clinically it is very difficult to make a diagnosis of amyloidosis on this patient, because the lesions are not typical. The clinical features of this case are expressed as an apparently normal but hyperpigmented skin, some areas of which are dotted with hypopigmentation (Fig 1). The histologic features consist of small amyloid deposits in the dermal papilla, which might be overlooked by hasty observation. These deposits stain positively with thiofavine T (Fig 2) and appear as amyloid fibers on ultrastructural studies.

A similar report of cutaneous amyloidosis manifested by "dyschromia" is reported.[1] Our case is unique because of (1) the amyloid deposits generalized throughout the body; (2) the familial nature of the disease; and (3) the presence of pulmonary and probably pancreatic involvement. Internal or systemic involvement of amyloidosis may be discovered by doing a skin biopsy on apparently normal-appearing skin and looking for amyloid deposits in the dermal papillae.

An interesting finding in our patient is the marble cake-like whorls of hypopigmentation on his flank. A biopsy specimen from this area was no different from the hyperpigmented and hypopigmented areas on the rest of his body. The hyperpigmented areas show increased melanin deposits in the epidermis with amyloid globules in the papillae. The hypopigmented areas show melanin incontinence in the dermis in addition to the amyloid deposits. The amount of amyloid appears directly proportional to the amount of dermal incontinence. On his flank the pattern is similar to incontinentia pigmenti or incontinentia pigmenti achromians or a nevoid abnormality. Perhaps there is a genetically or embryologically predisposed site at the flank for pigment incontinence to occur in a swirl pattern. Recently, Black and Maibach reported a case of amyloidosis masquerading as a nevoid abnormality resembling our case.[2]

LAWRENCE SOLOMON, MD: A patient may have two problems, as I think this patient does. There may very well be deposits of amyloid in the hyperpigmented areas. By no stretch of the imagination, however, can the term "incontinentia pigmenti" be applied to this patient's problem in order to encompass everything we see. Even the entity incontinentia pigmenti achromians does not apply appropriately to the hypopigmented areas. We have seen a number of patients, and others have been reported, in which large hypochromic areas are associated with mental retardation. Even in these patients the terminology is confused, although some have been called incontinentia pigmenti achromians. Nevus achromicus appears at birth, and an attentive nurse can usually identify the affected areas in the newborn infant. The hypopigmented areas in these nevi are not really achromic or vitiliginous. Pigment is usually present in reduced quantity. These hypochromic areas tan in the summer but usually not to the same degree as the surrounding skin. To sum up, I believe this patient has hypochromic nevus which has been caught up in a process resulting in the deposit of amyloid. Therefore, one should consider the patient as suffering from two problems: hypochromic nevus and hyperpigmentation with deposits of amyloid.

Look closely at these patients. Their dermatologist had them on a KOMEX®/KOMED® regimen.

Step 1 KOMEX®

"...toward keeping the skin meticulously clean...to decrease the usually concomitant oiliness."[1]

Cleanses thoroughly yet gently.

The detergent cleansing effect of Komex acne cleanser is uniquely enhanced with mild dissolving sodium borate particles (Scrubules) for effective yet gentle cleansing of the skin. Komex removes surface debris. Clears comedones. Cleans clogged pores. Unplugs hair follicles. And removes oils.

Mild abradancy won't damage skin.

"A frequently overlooked source of excessive friction is the practice of vigorous scrubbing in an attempt to wash acne away. The use of brushes and other scrubbing techniques can induce significant inflammatory lesions...Elimination of sources of excessive friction lead to rapid improvement[2]

The patented Komex Scrubules enable doctor and patient to control particle dissolution from 0-60 seconds, depending on water dilution. Acne patients can't overabrade with Komex. A significant exclusive.

Conditions the skin.

In fact, the skin *conditioning* effect of Komex acne soap is truly phenomenal. You can detect some of it in the patient photos. But it really must be seen – and felt.

Step 2 KOMED®

"...to peeling of the skin so that the follicular orifices are kept open."[1]

Employs a non-comedogenic form of sulfur.

Komed Lotion works beautifully with Komex.
"The sovereign remedy in the topical management of acne vulgaris is sulfur."[3]
"Sulfur...still the most effective remedy...In addition ...salicylic acid and other peeling chemicals are used in cosmetically elegant lotions..."[4]
The exclusive Komed formulation keeps skin dry and desquamating with salicylic acid and *non-comedogenic* sodium thiosulfate.

"Suspensions and creams containing elemental sulphur were shown to be capable of inducing comedones in the rabbit ear and on human backs."[5]

Has "excellent patient appeal."

"All of the patients liked the fact that (Komed) dries quickly to an invisible film...the female patients found that the lotion did not interfere with the use of non-oily cosmetics. Male patients also appreciated the lack of a masking effect, the absence of staining properties, and the fact that the lotions blend with natural skin tone."[6]

KOMEX®/KOMED®

Dermatology Section, AMA Annual Convention, San Francisco, June 18-22, 1977.—The Dermatology Section will include five courses, including cosmetics in dermatology, cutaneous surgery for the dermatologists, refresher dermatopathology, "live" case presentations for dermatologists, and dermatology for nondermatologists.

In addition, there will be a symposium on the practice and progress in sexually transmitted diseases, symposium on sunlight and skin, pros and cons, symposium on management of common dermatoses. Also, there will be 34 general papers on dermatological subjects. A no-host cocktail party will be held at the Fort Mason Officers' Club on Sunday evening, 6:00 to 8:00 PM, June 19, 1977.

The Program Director for the above meeting is Dr George W. Hambrick, Jr, University of Cincinnati Medical Center, 231 Bethesda Ave, Cincinnati, OH 45267. For information contact Robert J. McNamara, MD, 2828 Telegraph Ave, Berkeley, CA 94705.

Pediatric Dermatology.—On July 27-29, 1977, The Given Institute of Pathobiology, Aspen, Colo, will be giving a course in pediatric dermatology. This course is the second scientific meeting of the Society for Pediatric Dermatology, Inc, and is cosponsored by the Office of Postgraduate Medical Education of the University of Colorado School of Medicine. It is intended as an advanced seminar in pediatric dermatology, with didactic sessions, scientific papers, a "case of the year" session, clinicopathologic conferences, and a treatment panel.

Guest faculty include Robert A. Briggaman, MD, University of North Carolina; Blaise E. Favara, MD, The Children's Hospital, Denver; Loren E. Golitz, MD, University of Colorado; Elson B. Helwig, MD, Armed Forces Institute, Washington, DC; James T. Kushner, MD, University of Utah; Kenneth H. Neldner, MD, University of Colorado. In addition, eminent participating members of the Society are as follows: Nancy B. Esterly, MD, Michael Reese Medical Center, Chicago; Sidney Hurwitz, MD, Yale University; Alvin H. Jacobs, MD, Stanford University; Michael Jarratt, MD, Baylor University; James Rasmussen, MD, State University of New York at Buffalo; Lawrence Solomon, MD, University of Illinois; Samuel Weinberg, MD, New York University.

Registration fee is $125, including a nonrefundable administrative charge of $25. Colorado physicians and members of the Society for Pediatric Dermatology are cordially invited to attend for $100.

(A general dermatology meeting follows this meeting through Sunday, July 31. If interested in receiving a program for both meetings, please so indicate.)

Credit is approved for American Medical Association Category I. For further information, contact the Office of Postgraduate Medical Education, University of Colorado School of Medicine, 4200 E Ninth Ave, Denver, CO 80262, or call (303) 394-5241.

Annual Scientific Session.—The West Coast Allergy Society will hold its 16th annual Scientific Session, Dec 14-17, 1977, at the Camelback Inn, Scottsdale, Ariz. For further information, contact Robert L. Cutter, MD, Program Chairman, West Coast Allergy Society, 5210 SW Corbett Ave, Portland, ORE 97201.

Clinical Center Study of Patients With the Sézary Syndrome.—The cooperation of physicians is requested in the referral of patients with the Sézary syndrome (erythroderma, diffuse lymphocytes with cerebriform nuclei, and membrane properties of T cells) for a study being conducted by the National Cancer Institute at the Clinical Center, National Institutes of Health, Bethesda. For the purposes of this investigation, patients should have an abnormal lymphocyte count greater than 15,000 cu mm. Operative reports, pathology reports, and slides should be forwarded for review.

Patients will receive a complete evaluation of their neoplasm and their overall immune status. They may be considered for systemic chemotherapy if appropriate for the patient's stage of disease. This will require long-term follow-up in collaboration with the referring physicians.

A summary of the work-up, findings, and ultimate disposition will be sent to the referring physician.

Physicians interested in having their patients considered for admission may write or telephone: Dr Samuel Broder, Bldg 10, Rm 4N115, National Institutes of Health, Bethesda, MD 20014 (telephone: [301] 496-6653) or Dr Richard Fisher, Bldg 10, Rm 12N226, National Institutes of Health, Bethesda MD 20014 (telephone: [301] 496-4916).

DESCRIPTION

Synalar® (fluocinolone acetonide) has the
6α, 9α-difluoro-16α-hydroxyprednisolone-1

Synalar® Solution 0.01%—contains 0.01% fl
acetonide in propylene glycol with citric

Synalar® Ointment 0.025%—contains 0.02
acetonide in white petrolatum.

Synalar-HP® Cream—contains 0.2% fluoci
in a water-washable aqueous base of ste
alcohol, mineral oil, propylene glycol, sorl
stearate, polyoxyethylene sorbitan monos
citric acid, with methylparaben and prop
preservatives.

Synemol™ (fluocinolone acetonide) has th
6α, 9α-difluoro-16α-hydroxyprednisolone-1

The vehicle is a water-washable aqueous
stearyl alcohol, cetyl alcohol, mineral oil,
sorbitan monostearate, polyoxyethylene
stearate and citric acid.

INDICATIONS

For relief of the inflammatory manifestatio
steroid-responsive dermatoses.

CONTRAINDICATIONS

Topical steroids are contraindicated in vc
varicella.

Topical steroids are contraindicated in th
history of hypersensitivity to any of the com
preparation.

Synalar-HP Cream should not be used on
years of age.

PRECAUTIONS

If irritation develops, the product should b
appropriate therapy instituted.

In the presence of an infection the use of
antifungal or antibacterial agent should b
favorable response does not occur promp
steroid should be discontinued until the in
adequately controlled.

If extensive areas are treated or if the occl
used, the possibility exists of increased syst
of the corticosteroid and suitable precaut
taken.

Although topical steroids have not been re
adverse effect on pregnancy, the safety o
pregnant females has not absolutely bee
Therefore, they should not be used extens
patients, in large amounts, or for prolonge

Topical steroids are not for ophthalmic use

Synalar-HP Cream should not be used for
and the quantity per day should not exce
formulated material.

ADVERSE REACTIONS

The following local adverse reactions hav
with topicalcorticosteroids: burning, itchin
dryness, folliculitis, hypertrichosis, acneform
hypopigmentation.

Synalar Cream and Ointment, Synemol C

The following may occur more frequently
dressings than without such therapy: mace
secondary infection, skin atrophy, striae, m

ACNAVEEN® BAR

Soothes and cleans sensitive skin, and helps bring their guards down...

Hiding their embarrassment compounds the misery. Incessant picking and rubbing of acne lesions often causes more irritation. Urge them to wash with soap-free ACNAVEEN® Bar, logical adjunctive therapy in whatever treatment you've chosen:

- 2% salicylic acid and 2% sulfur provide a peeling and drying effect.
- Aveeno Colloidal Oatmeal soothes the skin and reduces irritation.

ACNAVEEN® BAR: Special mild cleansing bar for acne.

Available in 3.5 oz. bars

Cooper Cooper Laboratories, Inc., Wayne, New Jersey 07470

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

*Orentreich, N.: A clinical evaluation of two shampoos in the treatment of seborrheic dermatitis, J. Soc. Cosmet. Chem. 23:189 (March 3) 1972.

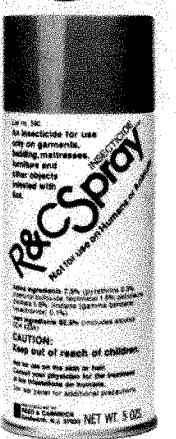
Now, m jor
the lice infestation.

advance to break reinfestation cycle.

Kills lice that remain on upholstery, bedding, carpeting...that may reinfest the patient or infest his family.



R&C Spray™ INSECTICIDE

with synergised pyrethrins and gamma benzene hexachloride

Pediculi and their ova can survive (for a short time) off the human host. Thus, even though the patient may have been successfully disinfested of lice on his person, immediate reinfestation is possible or a fresh infestation of other family members may occur.

To help break this infestation/reinfestation cycle, *when washing or dry cleaning is not possible,* R&C Spray can be applied to upholstery, bedding, carpeting and other objects where lice and their eggs are known to linger.

R&C Spray is specially formulated with synergised pyrethrins to provide effective parasite control. "Pyrethrins are exceptionally rapid in their effect upon insects...."[1] The other important active ingredient is gamma benzene hexachloride which, as a pediculicide, has been shown to be virtually 100% effective.[2]

After you have prescribed a specific for parasites on the scalp or body, complete the regimen with the specific for parasites off the body with R&C Spray Insecticide.

Caution: Not for use on humans or animals. Avoid spraying in eyes. May be absorbed through skin. Avoid breathing spray mist. Avoid contact with skin. In case of contact, wash immediately with soap and water. Avoid contamination of feed and foodstuffs. Harmful if swallowed. Vacate room after treatment and ventilate before reoccupying. **References: 1.** Osol, A. and Farrar, G.E., eds., *United States Dispensatory,* Philadelphia, J. B. Lippincott Co., 25th edition, 1960, p. 2012. **2.** *Patient Care* 7:94, Nov. 1, 1973.

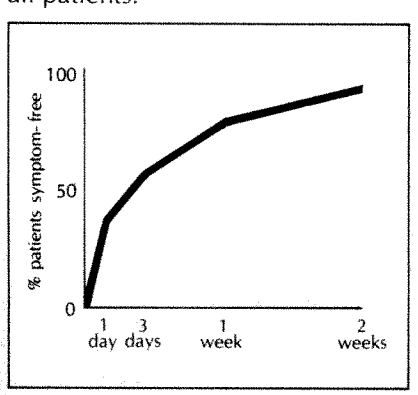
SWW-9340

The seven most important reasons to prescribe a topical antifungal. Right at your fingertips.

1 It is effective against the most prevalent fungal pathogens. MicaTin brand miconazole nitrate 2% offers exceptional effectiveness against the most difficult-to-treat pathogen—*Trichophyton rubrum*, and is equally effective against *Trichophyton mentagrophytes, Epidermophyton floccosum, Candida albicans* and *Malassezia furfur.*

2 It clears the most common fungal infections. MicaTin provides outstanding clinical and mycological efficacy in tinea pedis,* tinea corporis* and tinea cruris* as well as candidiasis and tinea versicolor.

3 It relieves symptoms quickly. Within 72 hours for the majority of patients. Within 1 to 2 weeks for virtually all patients.



4 It demonstrates effectiveness in extensive studies. Clinical studies† demonstrate the outstanding success rate of MicaTin in the treatment of tinea pedis, tinea corporis and tinea cruris, when used with the recommended dosage of twice daily for one month. At the end of therapy, 88—94% of the patients were clinically clear.

The clinical studies of patients with candidiasis and tinea versicolor are equally impressive. Nine out of ten patients with candidiasis or tinea versicolor were clinically and mycologically clear within two weeks—the recommended duration of treatment.

Pathogen	Infection	Conversion KOH	Culture	Clinical Clearance or Improvement
Trichophyton rubrum	Tinea pedis	82%	86%	88%
Trichophyton mentagrophytes / *Epidermophyton floccosum*	Tinea corporis / Tinea cruris	93%	90%	94%
Candida albicans	Candidiasis†	92%	86%	88%
Malassezia furfur	Tinea versicolor	89%	—	92%

5 Its low relapse rate promises an outstanding chance of cure. To prove how effective MicaTin really is in keeping fungal infections clear, we evaluated these same patients one month later (median).† Of the 121 patients who were clear of tinea pedis, tinea corporis and tinea cruris at the end of treatment *and* were available for follow-up, 92% showed no clinical or mycological recurrence of the original infection.

And of the 34 patients cleared of cutaneous candidiasis *and* available for follow-up, 91% were still clear two weeks later (median).

6 It has a low incidence of side effects. Reports of "burning" sensation, irritation and maceration with MicaTin have been few and isolated. Naturally, it should not be used in patients with known hypersensitivity to any of its ingredients.

7 It is economically priced. The retail price of MicaTin is usually lower than that of other prescription antifungals.

Introducing new
MicaTin Lotion
brand miconazole nitrate 2%
12 ml. and 30 ml. bottles
MicaTin cream
brand miconazole nitrate 2%
new 85 g. (3 oz.) tube
and familiar 1 oz. and 15 g. sizes

Description: MicaTin brand miconazole nitrate cream 2% and lotion 2% each contain miconazole nitrate‡ 2%, formulated into a water miscible base consisting of pegoxol 7 stearate, peglicol 5 oleate, mineral oil, benzoic acid, and butylated hydroxyanisole.

Actions: Miconazole nitrate is a synthetic antifungal agent which inhibits the growth of the common dermatophytes, *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* the yeast-like fungus, *Candida albicans,* and the organism responsible for tinea versicolor *(Malassezia furfur).*

Indications: For topical application in the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* in the treatment of cutaneous candidiasis (moniliasis), and in the treatment of tinea versicolor.

Contraindications: MicaTin has no known contraindications.

Precautions: If a reaction suggesting sensitivity or chemical irritation should occur, use of the medication should be discontinued.

For external use only. Avoid introduction of MicaTin brand miconazole nitrate cream 2% and lotion 2% into the eyes.

Adverse Reactions: There have been isolated reports of irritation, burning, and maceration associated with application of MicaTin.

Dosage and Administration: Sufficient MicaTin cream should be applied to cover affected areas twice daily (morning and evening) in patients with tinea pedis, tinea cruris, tinea corporis, and cutaneous candidiasis and once daily in patients with tinea versicolor. It is preferable to use MicaTin lotion in intertriginous areas; if the cream is used, it should be applied sparingly and smoothed in well to avoid maceration effects.

Early relief of pruritus (first week) and early clinical improvement (one to two weeks) have been seen in treatment of infections caused by common dermatophytes. Even though clinical improvement may be seen fairly soon after treatment is begun, *Candida* infections should be treated for two weeks and dermatophyte infections for one month in order to reduce the possibility of recurrence. If a patient shows no clinical improvement after a month of treatment, the diagnosis should be redetermined. Patients with tinea versicolor usually exhibit clinical and mycological clearing after two weeks of treatment.

How Supplied: MicaTin brand cream 2% containing miconazole nitrate at 2% strength is supplied in 1 oz., 15 g., and 3 oz. tubes. MicaTin brand lotion 2% containing miconazole nitrate at 2% strength is supplied in polyethylene squeeze bottles in quantities of 12 and 30 ml.

*When infecting organisms are *Trichophyton rubrum, Trichophyton mentagrophytes* and *Epidermophyton floccosum.*

†Data for tinea pedis is based on 4 weeks' therapy in 138 patients; for tinea cruris and tinea corporis—4 weeks' therapy in 50 patients; for tinea versicolor—2 weeks' therapy in 38 patients; for candidiasis—2 weeks' therapy in 23 patients and 4 weeks' therapy in 20 patients. (There was no significant difference in effectiveness between the two candidiasis groups.) Data on file, Dermatological Division, Johnson & Johnson.

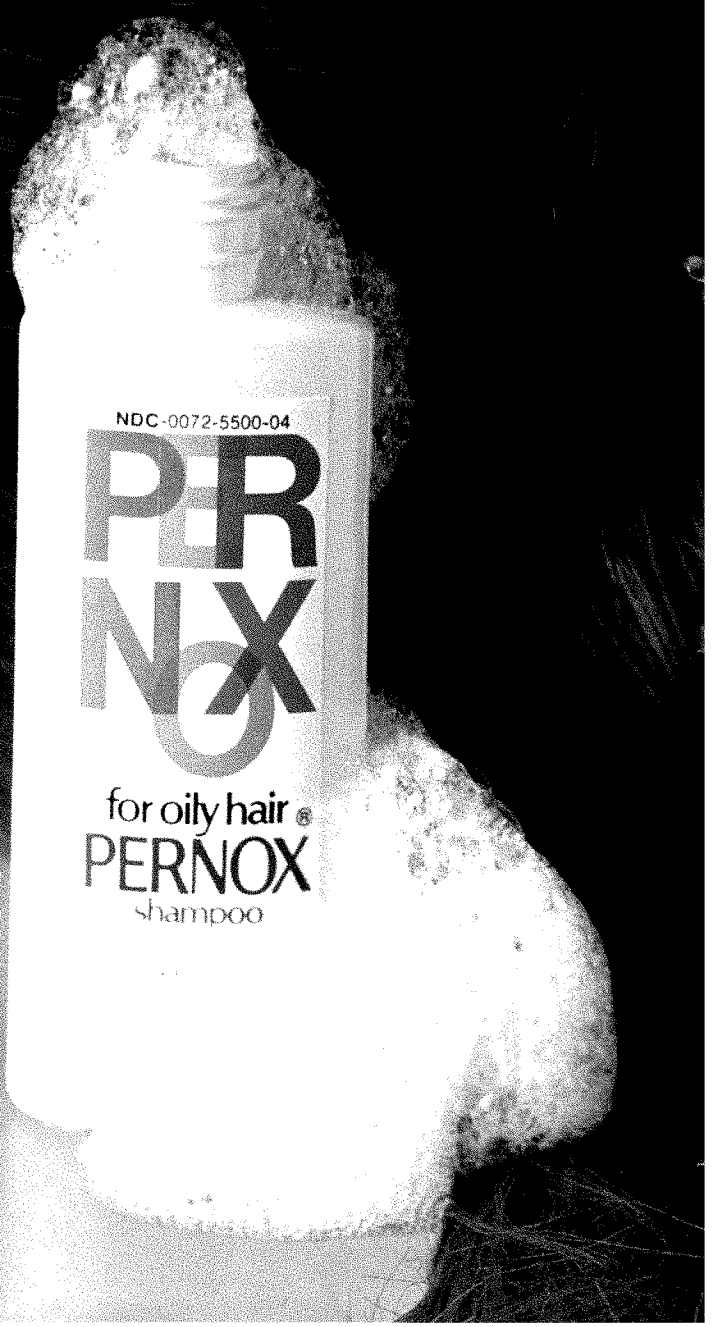
CONTEMPORARY AND EFFECTIVE

For seborrhea oleosa and the oily hair and scalp associated with acne



- Thorough cleansing of oily hair and scalp.
- Leaves patients' hair soft, manageable, fresh smelling.
- Elegant herbal scented shampoo.
- A special formulation designed to cleanse and condition oily hair.
- Its pH of 5.5 is gentle to the scalp.
- Can be used as often as necessary, preferably every day, to keep hair looking fresh and healthy.
- CONTAINS NO FORMALDEHYDE.

Supplied: 4 oz. and 8 oz. plastic bottles.

Pernox Shampoo® is adjunctive therapy especially formulated for oily scalps associated with acne.

New From Dermik

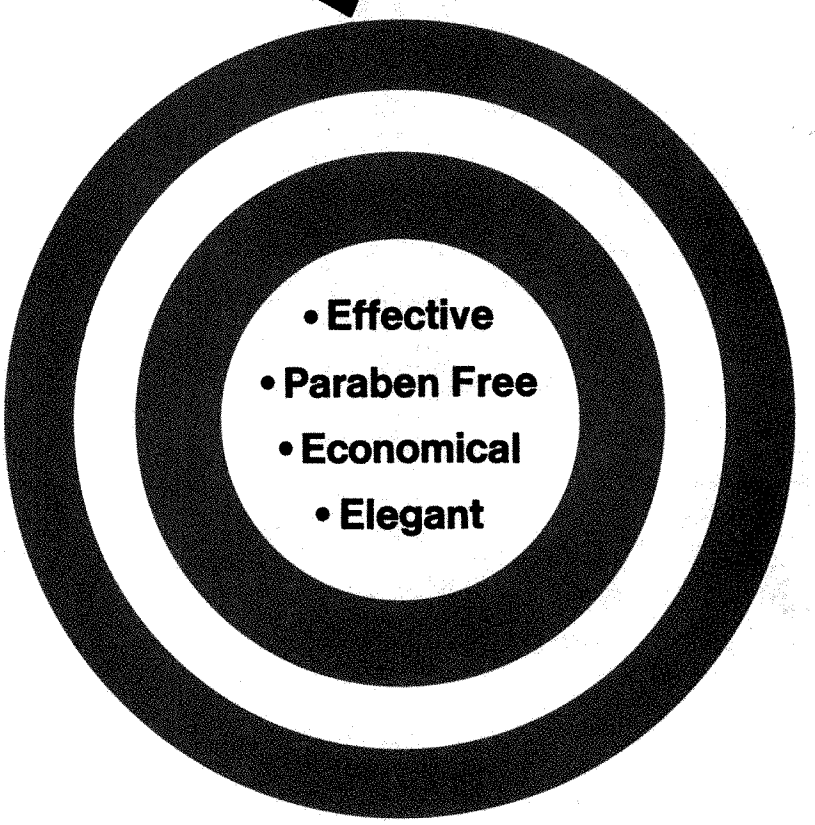
Hytone®

CREAM (HYDROCORTISONE)

2½%

hydrocortisone safety . . . new high potency . . .

- Atopic Dermatitis
- Severe Diaper Dermatitis
- Seborrheic Dermatitis
- Lichen Simplex Chronicus
- Pruritus Ani



Dermik

Dermik Laboratories, Inc., Fort Washington, Pa. 19034
WHERE RESEARCH AND ECONOMY COME FIRST!

DESCRIPTION – Hydrocortisone 2½%, 1% and ½% in a water-washable cream containing purified water, propylene glycol, isopropyl myristate, cholesterol and related sterols, cetyl alcohol, sorbic acid, glyceryl monostearate, polysorbate 60, sorbitan monostearate and polyoxyl 40 stearate.

ACTIONS – Topical corticosteroids are effective primarily because of their antiinflammatory, antipruritic, and vasoconstrictive actions.

INDICATIONS – For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: In viral diseases of the skin such as varicella and vaccinia and in patients with a history of hypersensitivity to any component. Not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.

WARNING: Should not be used extensively, in large amounts, or for prolonged periods in pregnancy.

PRECAUTIONS – If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

ADVERSE REACTIONS – The following local adverse reactions have been reported with topical corticosteroids, either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

DOSAGE AND ADMINISTRATION – Apply to affected areas 3 or 4 times daily.

HOW SUPPLIED: Tubes – ½ oz., 1 oz.

CAUTION – Federal law prohibits dispensing without prescription.

In vitro overlapping antibacterial action of Neosporin® Ointment (polymyxin B-bacitracin-neomycin).

Wellcome

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Neosporin® Ointment

(Polymyxin B-Bacitracin-Neomycin)

Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5,000 units; zinc bacitracin 400 units; neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs; in tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

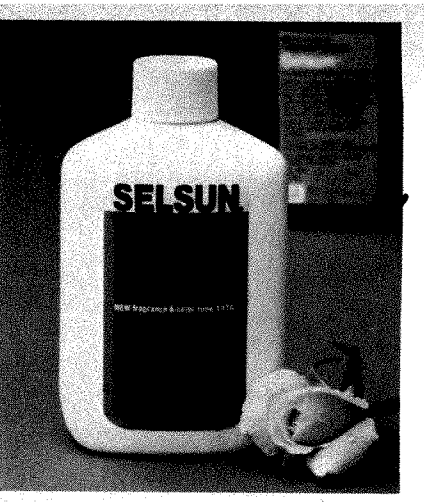
SUBSCRIPTION RATES: The yearly rate of the ARCHIVES OF DERMATOLOGY is as follows: United States and US Possessions, one year, $18; two years, $28; all other countries, one year, $28; two years, $38. Special yearly price to residents, interns and medical students in the United States and US Possessions, $9.

THE ARCHIVES OF DERMATOLOGY is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.



Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

Please address communications concerning accepted or published communications to: AMA Specialty Journals, 535 N Dearborn St, Chicago, IL 60610.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 600 Third Ave, New York, NY 10016, Area Code 212-867-6640.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

UVAL helps prevent sunburn by screening out the sun's rays most harmful to human skin. Offers sun-sensitive patients real protection with a broad range of ultraviolet absorption (220-350nm).
UVAL prevents burning, drying, wrinkling and freckling due to overexposure to the sun. Helps maintain softer, more youthful-looking skin. Provides protection with a low incidence of side effects.
UVAL has a creamy rich emollient base and may be used under makeup without loss of its sunscreening effectiveness.
UVAL frees your patients from the worry of painful sunburn. Lets them participate in outdoor work activity and enjoy fun in the sun year-round.
UVAL is alcohol-free and won't sting or dry skin. It protects with a nongreasy, almost invisible film that won't stain fabrics, skin or hair. Unlike PABA/Alcohol preparations, UVAL need not be applied one hour before sun exposure.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author, (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word can make an afflicted patient cringe. And, because of the capricious, unpredictable nature of the disease, the patient rarely knows where or when it will recur.

Obviously, the goal is control. And, though varied treatment modalities are available today, none offers universal

ficacy for all patients, all of the time.

Yet, very often a highly effective topical eroid, like Lidex, (fluocinonide) can elp stabilize psoriasis.

Lidex. A highly effective topical steroid ith anti-inflammatory, vasoconstrictive, ntipruritic actions.

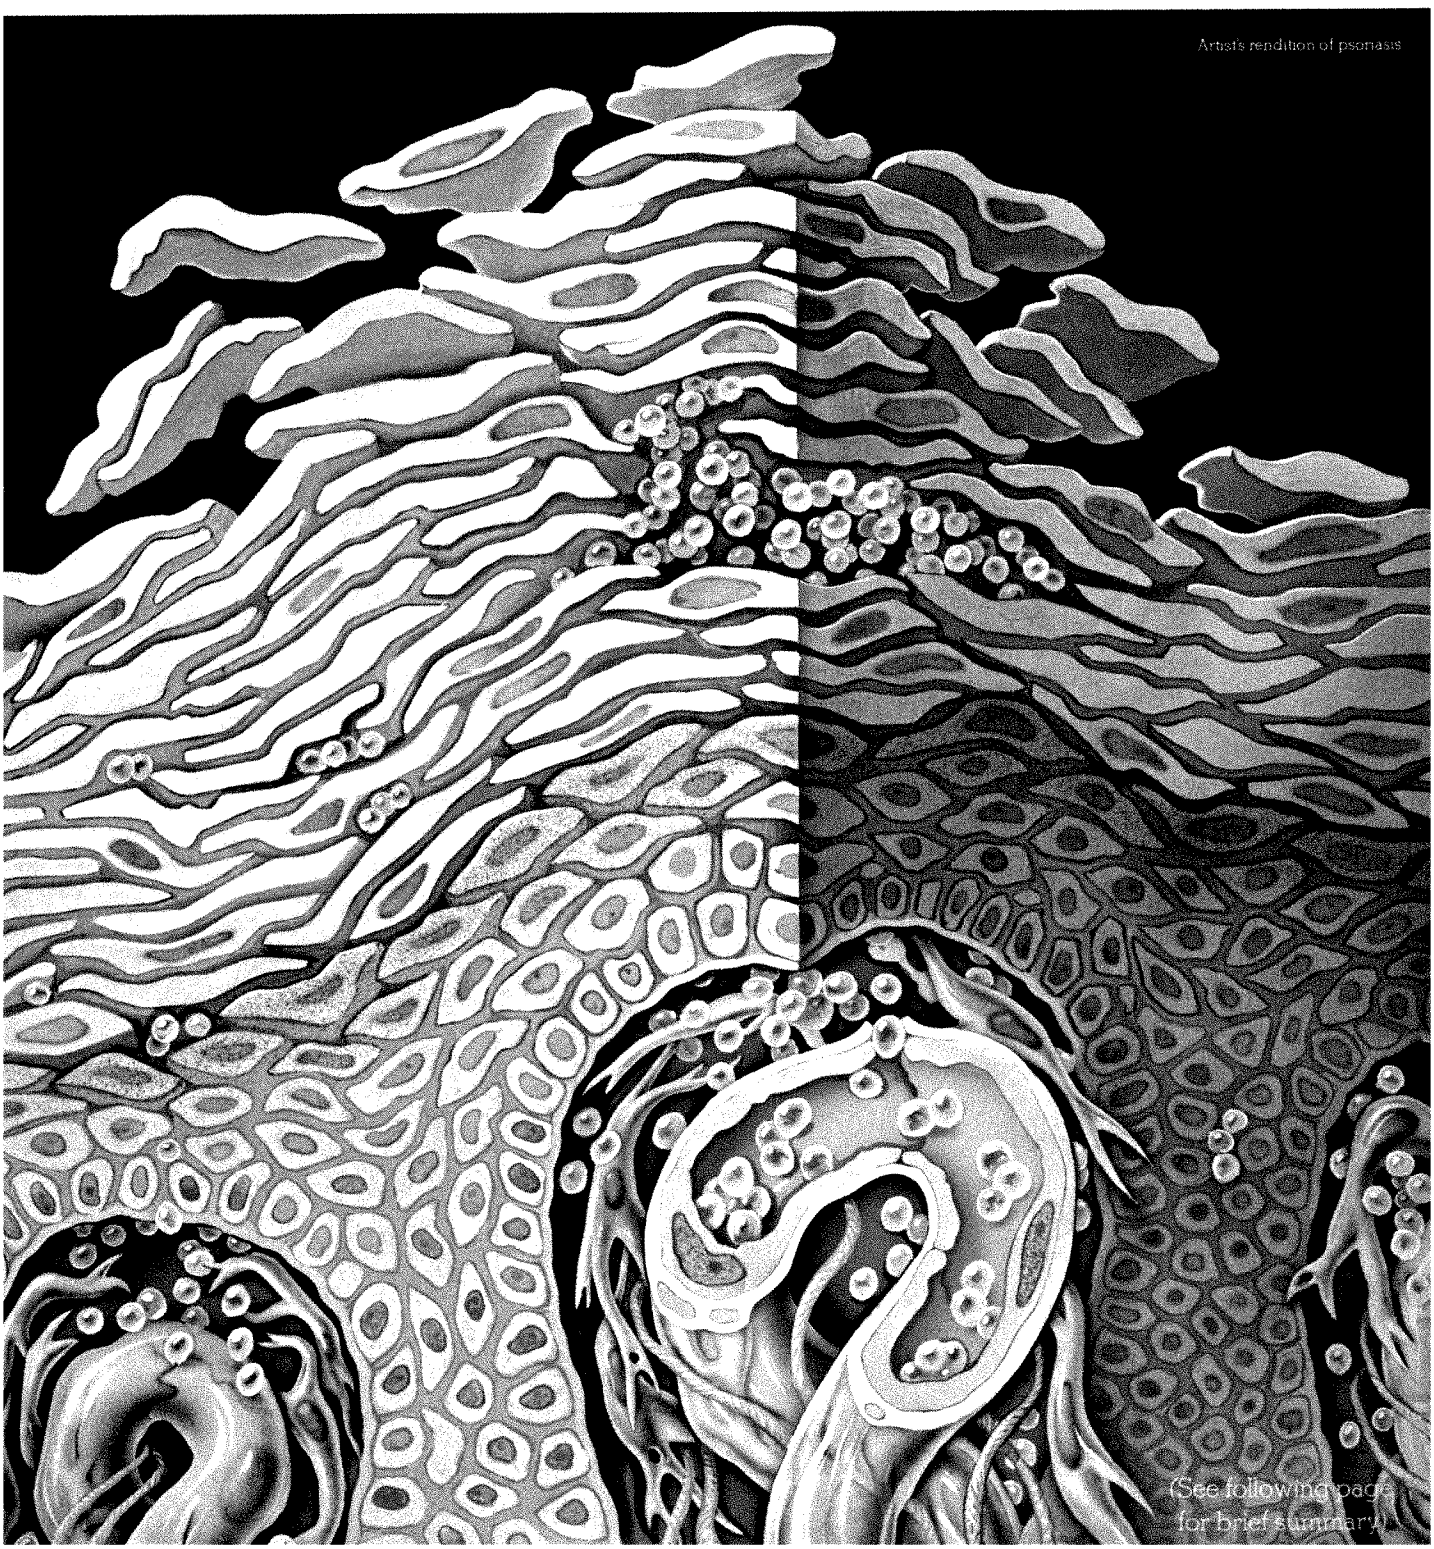
100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CALIFORNIA 94304



(See following page for brief summary)

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

SYNTEX
SYNTEX LABORATORIES, INC.
PALO ALTO, CALIFORNIA 94304

Vanoxide® Acne Lotion and Loroxide® Acne Lotion

Description: Vanoxide Acne Lotion contains (as dispensed) benzoyl peroxide 5% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion.

Loroxide Acne Lotion contains (as dispensed) benzoyl peroxide 5.5%, and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion, with "Dermik Color Blender" supplied separately.

How Supplied: Vanoxide—Bottles, 25 and 50 grams; Loroxide—Bottles, 25 grams

Vanoxide-HC® and Loroxide-HC® Lotions

Description: Vanoxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.0% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion containing purified water, propylene glycol, hydroxyethylcellulose, FD&C color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, and silica.

Loroxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.5% and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion containing purified water, propylene glycol, hydroxyethylcellulose, caramel color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, pH buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, silica, kaolin, talc and titanium dioxide, with "Dermik Color Blender" supplied separately.

Actions: Provides keratolytic, peeling and drying action.

Indications: An aid in the treatment of acne and oily skin.

Contraindications: Contraindicated for patients having known hypersensitivity to hydrocortisone, benzoyl peroxide, chlorhydroxyquinoline or any other component of this preparation. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia.

Warning—Usage in Pregnancy: Safety of use of topical steroids during pregnancy has not been absolutely established. Therefore, they should not be used extensively, or in large amounts or for prolonged periods of time on pregnant patients.

Precautions: For external use only. Keep away from eyes. Discontinue use if irritation develops. Use of appropriate antifungal or antibacterial agents should be instituted in presence of infection. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Observe patients carefully for possible local irritation or sensitization during long-term topical therapy. Apply with caution on neck and/or other sensitive areas. There may be a slight, transitory stinging or burning sensation on initial application which invariably disappears on continued use. Ultraviolet and cold quartz light should be employed in lesser amounts, as this lotion is keratolytic and drying. Harsh, abrasive cleansers should not be used simultaneously with this lotion. Colored or dyed garments may be bleached by the oxidizing action of benzoyl peroxide. Chlorhydroxyquinoline may cause temporary light-yellowish skin staining in rare cases. Keep out of the reach of children.

Adverse Reactions: Local adverse reactions reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneiform eruptions, and hypopigmentation. The sensitizing potential of benzoyl peroxide and chlorhydroxyquinoline are low; but they can produce allergic reaction. Reduce amount and frequency of application if excessive redness or peeling occurs.

How Supplied: Bottles, 25 grams.

Caution: Federal law prohibits dispensing without prescription.

5-Benzagel® and 10-Benzagel® Acne Gels

Description: 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent gel containing colloidal magnesium aluminum silicate, hydroxypropyl methylcellulose, citric acid, fragrance, and purified water.

Action: Provides drying, desquamative and antiseptic activity.

Indication: An aid in the treatment of acne.

Dosage and Administration: Wash affected areas prior to application. Apply once or more daily or as directed by physician.

Contraindications: Should not be used by patients having known sensitivity to either benzoyl peroxide or polyoxyethylene lauryl ether.

Precautions: For External Use Only. Not for ophthalmic use. Keep away from eyes and mucosae. Very fair individuals should begin with a single application at bedtime allowing overnight medication. May bleach colored fabrics. Keep this and all other medications out of the reach of children.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Plastic tubes, 1½ oz. and 3 oz.

Dermik

DERMIK LABORATORIES, INC.
Fort Washington, Pa., U.S.A. 19034

Now!... a full family of products for intensive acne care from

Dermik

originator and leader in Benzoyl Peroxide Acne Therapy at practical patient cost

For Benzoyl Peroxide Acne Therapy with superior, penetrating, antibacterial action...

INVISIBLE

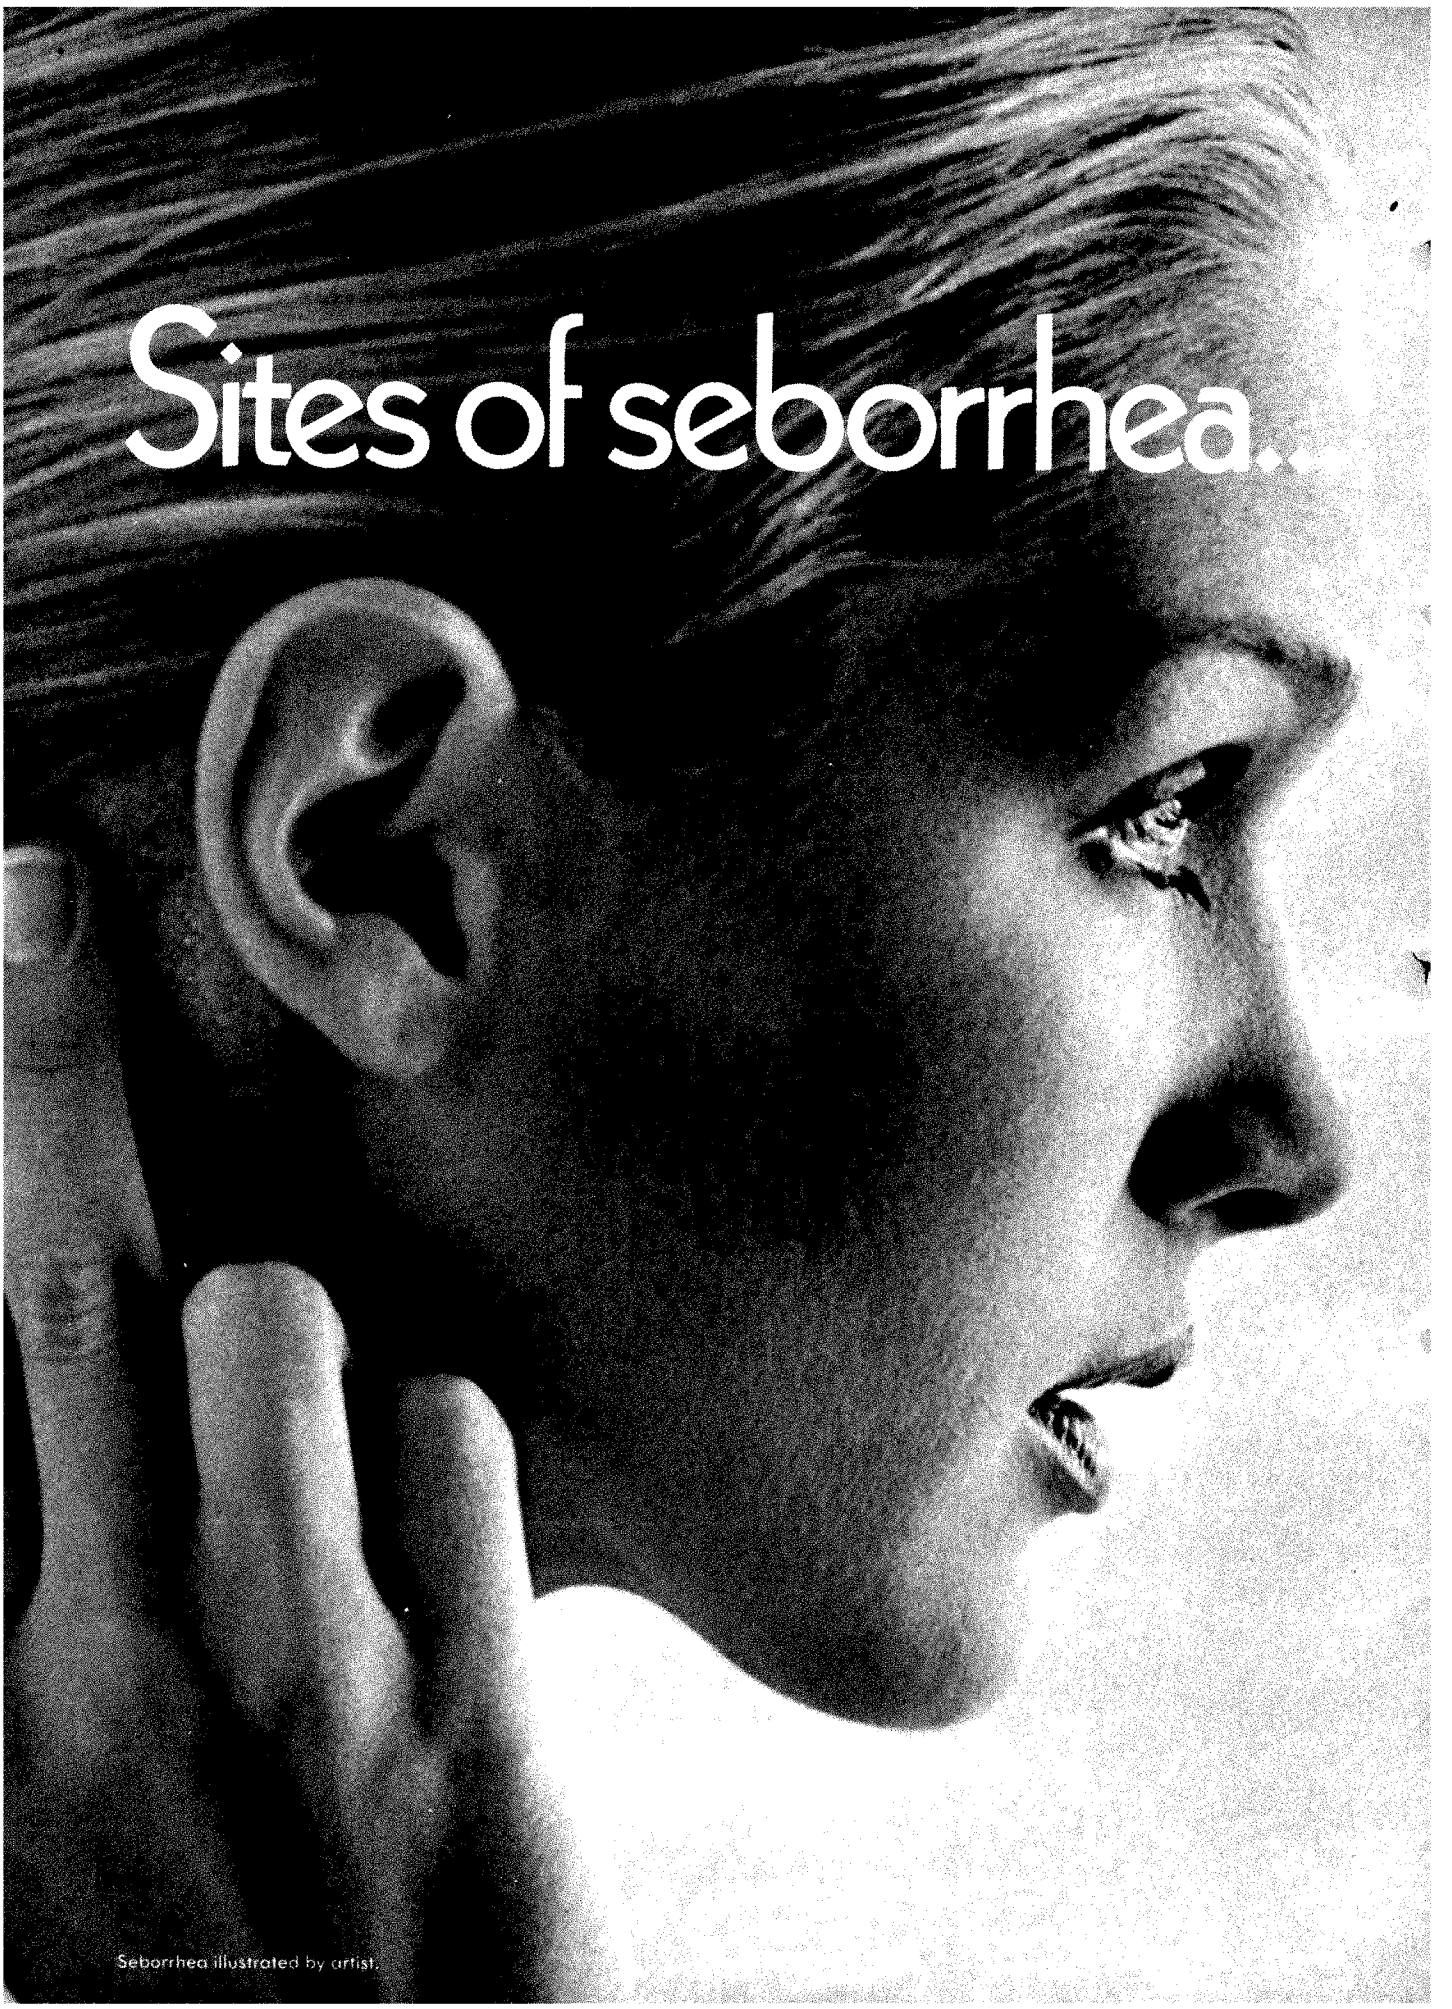
- Vanoxide® and Vanoxide-HC® are indicated for severe, recalcitrant, oily acne

FLESH-TINTED

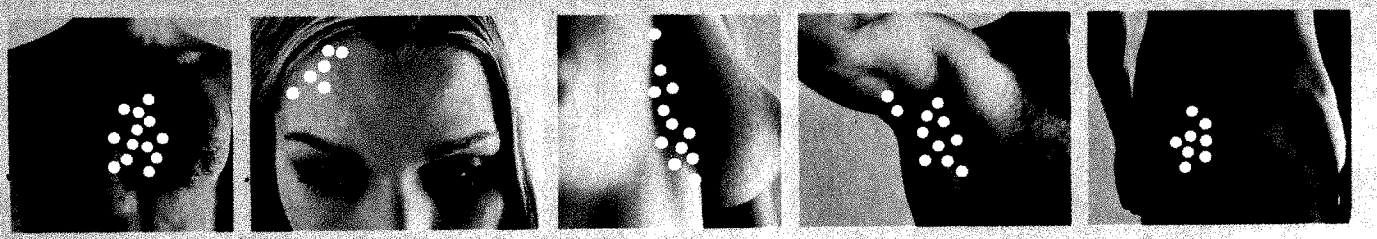
- Loroxide® and Loroxide-HC® are the only tinted benzoyl peroxide products available, and they can be used as a daily make-up. These products provide the same formulation and therapeutic benefits as Vanoxide and Vanoxide-HC.
- Chlorhydroxyquinoline—benzoyl peroxide lotions provide substantially greater action than benzoyl peroxide alone. It is topical acne medication with proven ability to reduce *C. acnes* within the pilosebaceous structures.

For Benzoyl Peroxide Therapy in acne where maximal drying effect is desired...

- 5 Benzagel® and 10 Benzagel® contain 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent, colloidal magnesium aluminum silicate gel vehicle.
- This combination provides superior drying action and achieves dramatic improvement in comedone and papular stages of acne... WITHOUT EXCESSIVE ERYTHEMA OR IRRITATION.



Sites of seborrhea...
Seborrhea illustrated by artist.



spots for Uticort™ (betamethasone benzoate)

a highly effective topical steroid in a special base

UTICORT contains the fluorinated corticosteroid ester — betamethasone benzoate 0.025% — in a specially formulated, clear, self-liquefying gel base to increase steroid activity.

Patients with seborrheic dermatitis treated with UTICORT improved 86% in an average of 11.6 days.

liquefies on application for better surface contact

UTICORT is especially valuable in the treatment of seborrheic dermatitis on hairy areas of the body.

cosmetically acceptable

UTICORT dries to a clear film and can be used confidently on either smooth or hairy skin areas. Moreover, it is greaseless, nonstaining, and nonsticky.

preservative free

Contains no parabens or other potentially sensitizing preservatives.

Brief summary of prescribing information

INDICATIONS. Uticort Gel (betamethasone benzoate) is intended for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia. Topical steroids are contraindicated in patients with a history of sensitivity to any of the components of the preparation.

This preparation is not for ophthalmic use.

PRECAUTIONS. If irritation develops, the gel should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid, and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, or in large amounts, or for prolonged periods of time.

Due to the alcohol content of the vehicle, Uticort Gel (betamethasone benzoate) may cause mild, transient stinging without irritation if used on excoriated skin.

ADVERSE REACTIONS. The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruptions, and hypopigmentation.

DOSAGE AND ADMINISTRATION. Apply to affected areas two to four times daily as needed.

HOW SUPPLIED. N 0071-3025 Uticort Gel is supplied in 15-g and 60-g tubes.

Caution: Federal law prohibits dispensing without prescription.

CUT THE GRISEOFULVIN DOSE IN HALF

Gris-PEG®
(griseofulvin ultramicrosize)
Tablets 125 mg

For fungal infections sensitive to griseofulvin

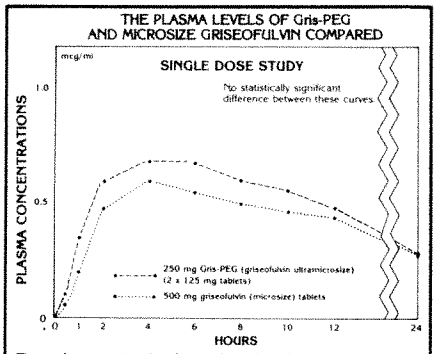
- Only half the dose required*
- Absorption nearly complete without fatty meals
- Once-a-day or b.i.d. dosage
- Reduced cost for patients

*250 mg of Gris-PEG® provides plasma levels equivalent to those obtained with 500 mg microsize griseofulvin. This improved absorption permits the oral intake of half as much griseofulvin but there is no evidence at this time that this confers any clinical difference in regard to safety or efficacy.

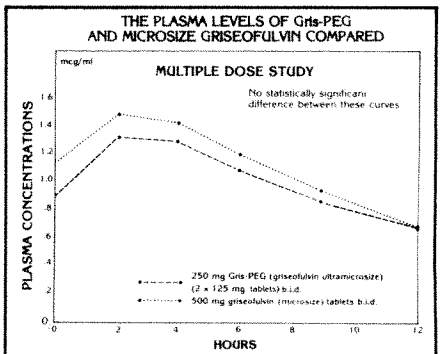
Dorsey LABORATORIES
Division of Sandoz, Inc.
LINCOLN, NEBRASKA 68501

Please see other side for full prescribing information.

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
The ½ dose griseofulvin.



Based on a single dose double-blind bioavailability study conducted in 24 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels. There is no significant difference between peak plasma levels, times to peak, and areas under the curve. Gas chromatographic assay.



Based on a double-blind multiple dose steady state crossover bioavailability study conducted in 17 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels obtained on days 9, 11 and 13. There is no significant difference between times to peak, peak plasma levels, and areas under the curve. Gas chromatographic assay.

DESCRIPTION

Griseofulvin is an antibiotic derived from a species of *Penicillium*.

Gris-PEG is an ultramicrocrystalline solid-state dispersion of griseofulvin in polyethylene glycol 6000.

Gris-PEG tablets differ from griseofulvin (microsize) tablets USP in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsize griseofulvin.

ACTION

Microbiology: Griseofulvin is fungistatic with *in vitro* activity against various species of *Microsporum, Epidermophyton* and *Trichophyton*. It has no effect on bacteria or other genera of fungi.

Human Pharmacology: The peak plasma level found in fasting adults given 0.25 g of Gris-PEG occurs at about four hours and ranges between 0.37 to 1.6 mcg/ml.

Comparable studies with microsize griseofulvin indicated that the peak plasma level found in fasting adults given 0.5 g occurs at about four hours and ranges between 0.44 to 1.2 mcg/ml.

Thus, the efficiency of gastrointestinal absorption of the ultramicrocrystalline formulation of Gris-PEG is approximately twice that of conventional microsized griseofulvin. This factor permits the oral intake of half as much griseofulvin per tablet but there is no evidence, at this time, that this confers any significant clinical differences in regard to safety and efficacy.

Griseofulvin is deposited in the keratin precursor cells and has a greater affinity for diseased tissue. The drug is tightly bound to the new keratin which becomes highly resistant to fungal invasions.

INDICATIONS

Gris-PEG (griseofulvin ultramicrosize) is indicated for the treatment of the following ringworm infections.

Tinea corporis (ringworm of the body)
Tinea pedis (athlete's foot)
Tinea cruris (ringworm of the thigh)
Tinea barbae (barber's itch)
Tinea capitis (ringworm of the scalp)
Tinea unguium (onychomycosis; ringworm of the nails)

when caused by one or more of the following genera of fungi:

Trichophyton rubrum
Trichophyton tonsurans
Trichophyton mentagrophytes
Trichophyton interdigitalis
Trichophyton verrucosum
Trichophyton megnini
Trichophyton gallinae
Trichophyton crateriform
Trichophyton sulphureum
Trichophyton schoenleini
Microsporum audouini
Microsporum canis
Microsporum gypseum
Epidermophyton floccosum

NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.

The use of the drug is not justified in minor or trivial infections which will respond to topical agents alone.

Griseofulvin is *not* effective in the following:

Bacterial infections
Candidiasis (Moniliasis)
Histoplasmosis
Actinomycosis
Sporotrichosis
Chromoblastomycosis
Coccidioidomycosis
North American Blastomycosis
Cryptococcosis (Torulosis)
Tinea versicolor
Nocardiosis

CONTRAINDICATIONS

This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.

WARNINGS

Prophylactic Usage: Safety and Efficacy of Griseofulvin for Prophylaxis of Fungal Infections Has Not Been Established.

Animal Toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.

In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.

Usage in Pregnancy: The safety of this drug during pregnancy has not been established.

Animal Reproduction Studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.

Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

PRECAUTIONS

Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic and hematopoietic, should be done.

Since griseofulvin is derived from species of *Penicillium*, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.

Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.

Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.

Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

ADVERSE REACTIONS

When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion and impairment of performance of routine activities.

Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.

When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

DOSAGE AND ADMINISTRATION

Accurate diagnosis of the infecting organism is essential. Identification should be made either by direct microscopic examination of a mounting of infected tissue in a solution of potassium hydroxide or by culture on an appropriate medium.

Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. Representative treatment periods are—*tinea capitis*, 4 to 6 weeks; *tinea corporis*, 2 to 4 weeks; *tinea pedis*, 4 to 8 weeks; *tinea unguium*—depending on rate of growth—fingernails, at least 4 months; toenails, at least 6 months.

General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required particularly in treatment of *tinea pedis*. In some forms of athlete's foot, yeasts and bacteria may be involved as well as fungi. Griseofulvin will not eradicate the bacterial or monilial infection.

An oral dose of 250 mg of Gris-PEG (griseofulvin ultramicrosize) is biologically equivalent to 500 mg of griseofulvin (microsized), USP (see ACTION Human Pharmacology).

Adults: A daily dose of 250 mg will give a satisfactory response in most patients with *tinea corporis, tinea cruris* and *tinea capitis*. One 125 mg tablet twice per day or two 125 mg tablets once per day is the usual dosage. For those fungal infections more difficult to eradicate such as *tinea pedis* and *tinea unguium*, a divided daily dose of 500 mg is recommended. In all cases, the dosage should be individualized.

Children: Approximately 5 mg per kilogram (2.5 mg per pound) of body weight per day is an effective dose for most children. On this basis, the following dosage schedule for children is suggested:

Children weighing over 25 kilograms (approximately 50 pounds)—125 mg to 250 mg daily.

Children weighing 15-25 kilograms (approximately 30-50 pounds)—62.5 mg to 125 mg daily.

Children 2 years of age and younger—dosage has not been established.

Dosage should be individualized, as is done for adults. Clinical experience with griseofulvin in children with *tinea capitis* indicates that a single daily dose is effective. Clinical relapse will occur if the medication is not continued until the infecting organism is eradicated.

HOW SUPPLIED

Gris-PEG (griseofulvin ultramicrosize) Tablets (white) differ from griseofulvin (microsize) tablets (USP) in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsized griseofulvin. Two 125 mg tablets of Gris-PEG are biologically equivalent to 500 mg of microsized griseofulvin. In bottles of 100 and 500 scored, film-coated tablets.

O- -YB

When patient acceptance is half the problem

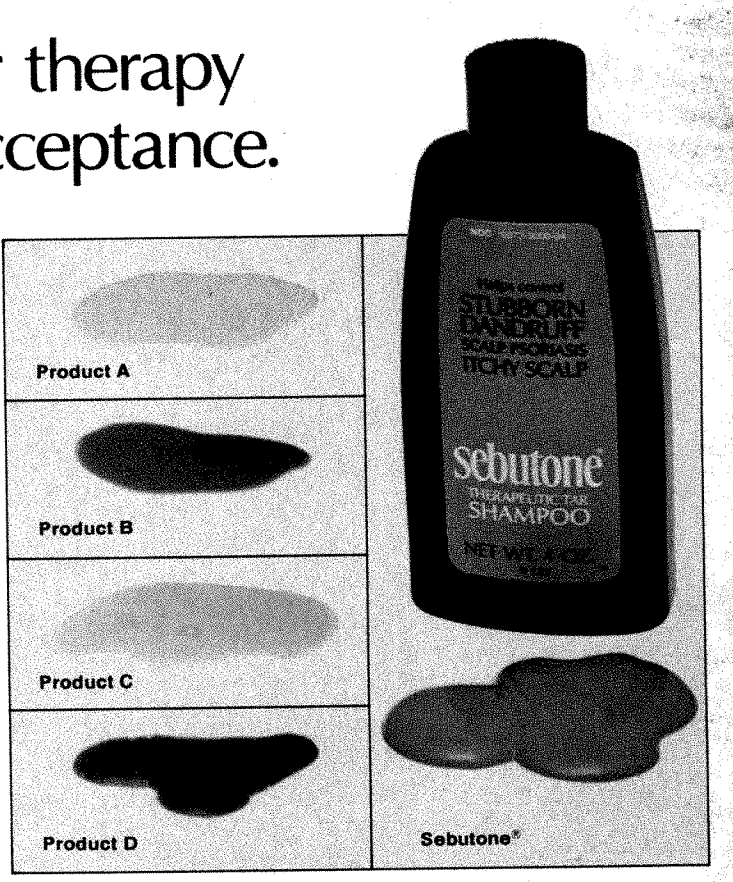
sebutone®

is the answer.

Tar is effective therapy, but it has one big drawback . . . most shampoos look like tar and, worst of all, they smell like it, too.

Sebutone® provides tar therapy with unique patient acceptance.

- Itching usually stops after the first shampoo.
- It has a clean, fresh odor patients will like.
- It is a rich, lathering shampoo with a pleasant color.
- It contains the first chemically and biologically standardized tar, developed by Westwood.
- Sebutone's tar is bioassayed to insure therapeutic activity from batch to batch.
- Available in both lotion and cream.
- In addition to 0.5% Westwood® Tar, Sebutone contains 2% sulfur and 2% salicylic acid, for increased effectiveness.
- Wood's light shows that microfine particles remain on the scalp for up to three days to provide sustained antiseborrheic action.



sebutone® Therapeutic Tar Shampoo

Substantive therapy...proven by Wood's light.

Available—Sebutone in 4 and 8 oz. bottles; Sebutone Cream in 4 oz. tubes.

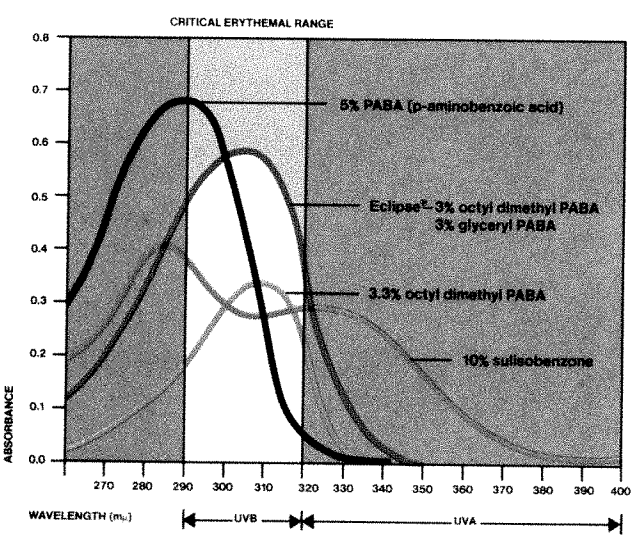
ECLIPSE®

(3% glyceryl PABA and 3% octyl dimethyl PABA)

For your patients

who can't-or won't-stay out of the sun.

For some, it's occupation. For others, the social desirability of a tan. Whatever the reason, many of your patients may be spending more time in the sun than you'd like.



Unique Eclipse formulation combines two PABA derivatives for maximum UVB absorption.

They need Eclipse—a highly effective sunscreen that works immediately upon application, resists wash-off, and contains our exclusive Aquacare® base to help relieve sun and wind-dried skin.

Can other sunscreens do all that? Take a minute to read the labels: we're confident you'll recommend Eclipse.

- Absorbs more than 99% of erythemogenic solar UVB.
- Spreads smoothly and predictably for even protection.
- Permits slow tanning.
- Resists wash-off; protects after swimming or sweating.
- Formulated in Aquacare® to relieve sun and wind-dried skin.

...safe for your patients to use, ...effective and less traumatic than cryosurgery or curettage[1]

Duofilm®

(Salicylic Acid, USP, 16.7% and Lactic Acid, USP, 16.7% in Flexible Collodion, USP)

for warts

et remedies for warts are almost as ommon as warts themselves. How- ver, one specific formulation has gain clinically proven its value.

. B. Rees reported, *"My favorite wart emedy is . . . equal parts of salicylic cid and lactic acid in four parts of lexible collodion (Duofilm)".*[2]

Bunney and associates find the Duofilm ormula, used at home, at least as ffective as, and less traumatic than, ryotherapy and curettage.[1]

Arndt[3], in a double-blind controlled tudy of patients with multiple warts, onfirmed Bunney's findings.

Duofilm is safe and simple to use. Special patient instruction pads and upplies of Duofilm for your treatment able are available on request.

omposition: Salicylic Acid, USP, 16.7% and Lactic Acid, USP, 6.7% in Flexible Collodion, USP.

ndications: DUOFILM is indicated as a keratolytic agent for the re- oval of benign epithelial tumors such as common warts.

osage and Administration: Prior to the application of DUOFILM, oak the affected area in hot water for at least five minutes. Dry horoughly with a clean towel.

pply DUOFILM directly to the wart using the plastic applicator. Each rop should be permitted to dry before re-application of the liquid. are should be taken to see that DUOFILM is not applied to the sur- ounding skin. A Band-Aid® or similar bandage should then be pplied lightly.

reatment should take place once daily and continue as directed by hysician.

ontraindications: Diabetics or patients with impaired blood circu- ation should not use DUOFILM. Do not use on moles, birthmarks or nusual warts with hair growing from them.

recautions: For external use only.

UOFILM is highly flammable and should be kept away from fire or lame. Keep bottle tightly capped when not in use. Store at con- rolled room temperature.

f spilled on mucous membranes or in eyes, flush with water, remove recipitated collodion, and flush with water for an additional 15 inutes.

eep this and all medication out of the reach of children.

ow Supplied: DUOFILM is available in ½ oz. bottles with plastic pplicators.

aution: Federal law prohibits dispensing without a prescription.

Persa-Gel™
(BENZOYL PEROXIDE)
Unique Acetone Gel 5% and 10%

TPC
TEXAS PHARMACAL COMPANY
San Antonio, Texas 78296

Unique acetone base enhances stability and cosmetic acceptability.

Two and one-half year dating
No refrigeration required

CAUTION: Federal law prohibits dispensing without prescription.
DESCRIPTION: Persa-Gel™ 5% contains 5% benzoyl peroxide; Persa-Gel™ 10% contains 10% benzoyl peroxide; in a gel base containing acetone, carboxyvinyl polymer, triethanolamine, sodium lauryl sulfate, propylene glycol and purified water.
ACTIONS: Benzoyl peroxide is primarily effective because of its drying, peeling and antiseptic action.
INDICATION: For adjunctive topical therapy of acne vulgaris.
CONTRAINDICATIONS: Benzoyl peroxide is contraindicated in patients with acute inflammation and in patients with a history of hypersensitivity to any of the components of the preparation.
PRECAUTIONS: If excessive irritation develops, discontinue use and institute appropriate therapy. After the reaction clears, treatment may often be resumed with less frequent applications. Avoid contact with eyes, eyelids, lips and other mucous membranes, and anterior neck. May bleach hair and colored fabrics.
ADVERSE REACTIONS: Allergic contact dermatitis and severe erythema with crusting have been reported with topical benzoyl peroxide.
DOSAGE AND ADMINISTRATION: Persa-Gel™ (benzoyl peroxide) should be applied thinly to cover affected area after cleansing with non-medicated soap and water or a degreaser. Initial application once daily before bedtime is recommended, increasing to twice daily as tolerance develops. Feelings of warmth and stinging and slight erythema may be noted initially. It is advisable to initiate therapy with Persa-Gel™ 5% shifting to the use of Persa-Gel™ 10% after 3 or 4 weeks, or earlier if tolerance to the 5% has been determined. Therapeutic results are usually seen within 2 weeks with continued improvement thereafter.
HOW SUPPLIED: Persa-Gel™ 5% 1.5 oz. tubes (NDC0064-8610-31)
Persa-Gel™ 10% 1.5 oz. tubes (NDC0064-8600-31)

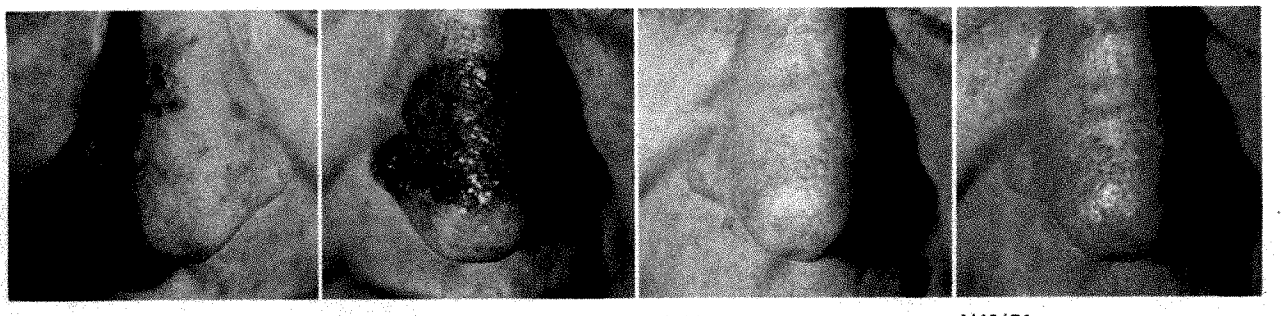
ROCHE

Roche Laboratories announces an additional therapeutic application for Efudex® 5% Cream fluorouracil/Roche

now indicated for superficial basal cell carcinoma



8/8/69
Before treatment a superficial, scaly, slightly excoriated lesion was present. Biopsy revealed the lesion to be a superficial basal cell carcinoma.

9/25/69
After 7 weeks of treatment with Efudex (fluorouracil) 5% Cream, lesion site is clearly delineated, markedly erythematous; surrounding skin shows no reaction to medication. Treatment terminated.

12/10/70
Follow-up approximately 14 months after treatment; healing has occurred with minimal scarring.

4/18/74
Patient has been followed continuously since treatment. **No evidence of recurrence.**

Efudex (fluorouracil) 5% Cream is recommended as an effective topical alternative to surgery for multiple lesions and difficult treatment sites.

A proven cytotoxic agent that exerts a marked effect on cells that grow more rapidly.

Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity. Normal tissue rarely affected. Convenient, economical b.i.d. application.

Prolonged exposure to ultraviolet light may accelerate reaction to medication. If an occlusive dressing is used, there may be an increase in the incidence of inflammatory reactions in the adjacent normal skin.

An exclusive Roche formulation

Efudex® 5% Cream

fluorouracil/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).
Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.
Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.
Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.
Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity **(only 5% strength recommended)** to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.
How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

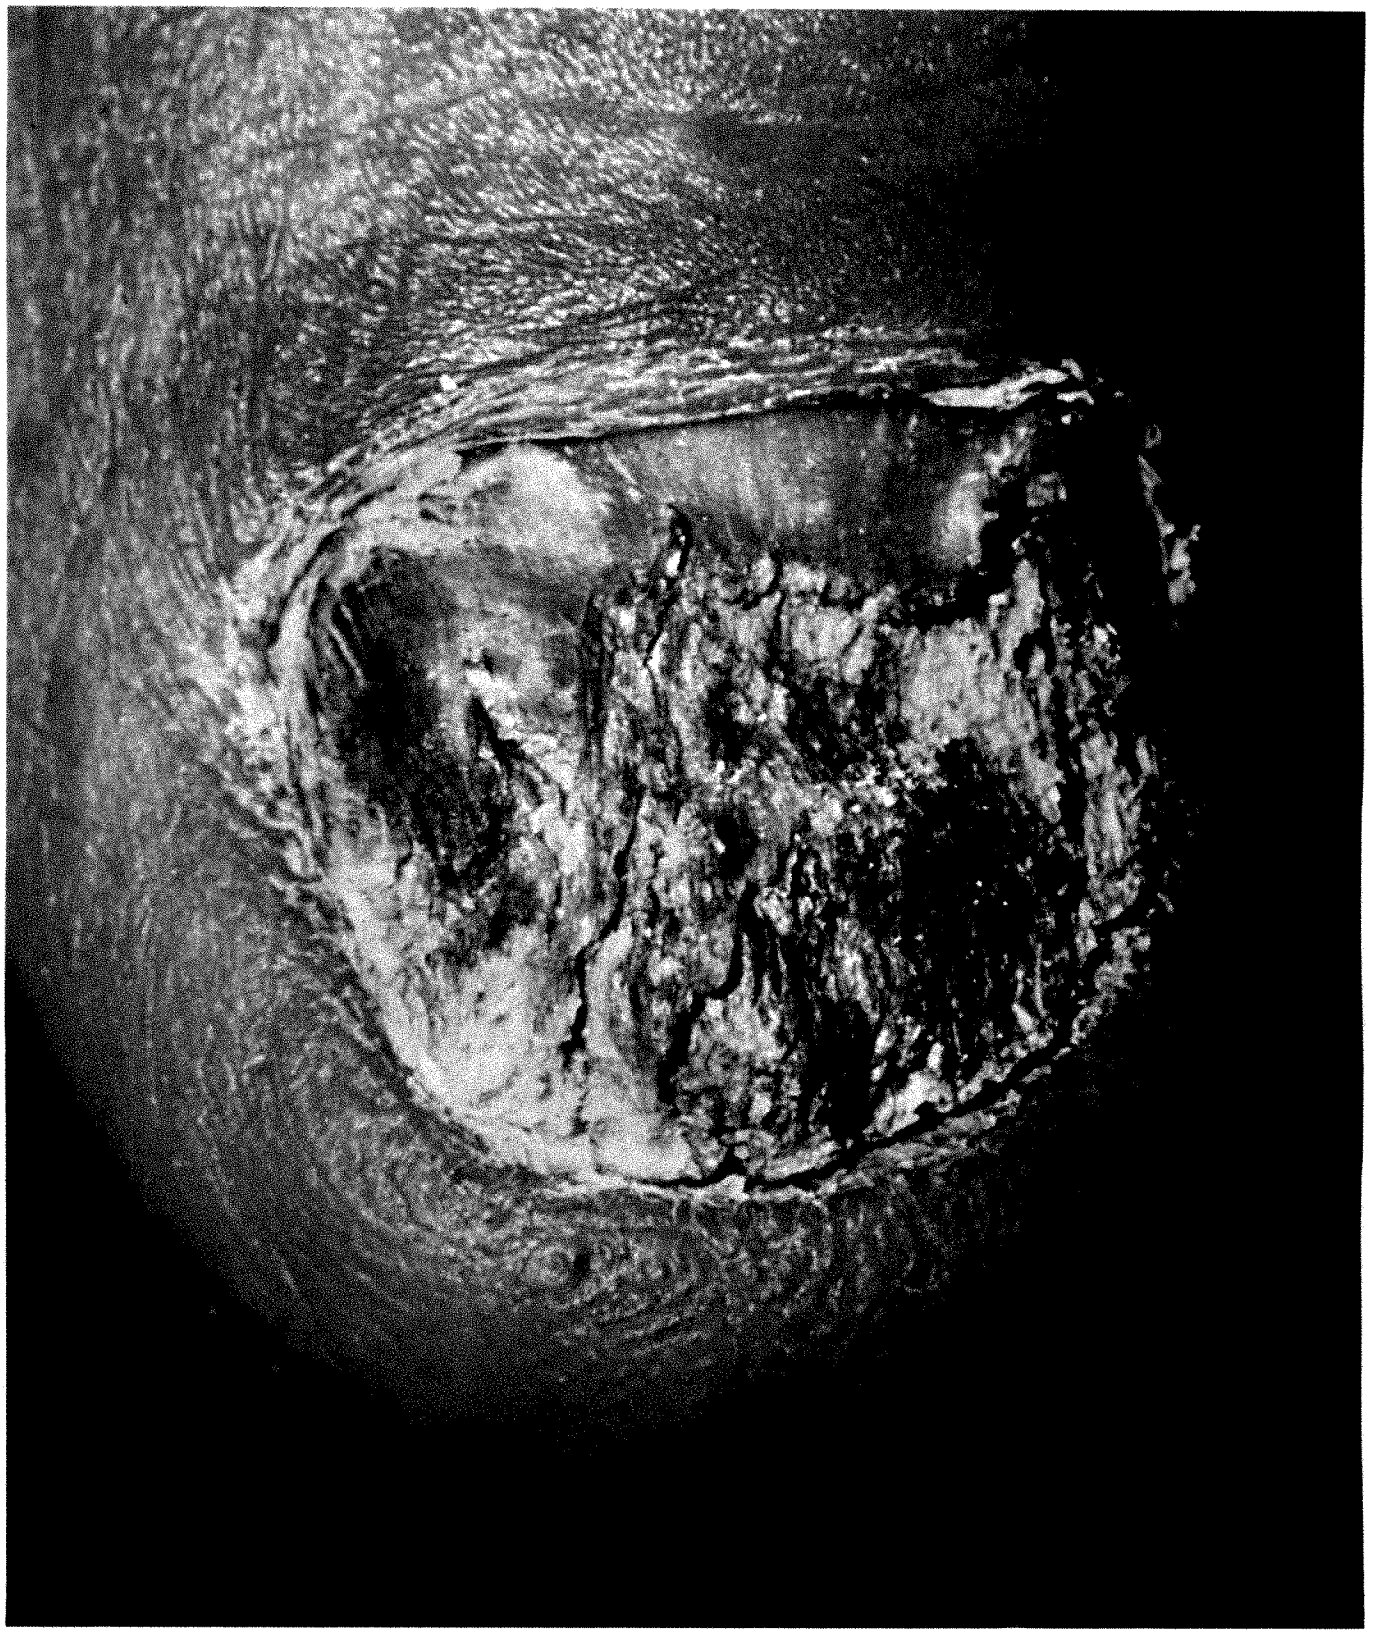
Gets to deep fungal infections



Actual photograph of tinea unguium infection (onychomycosis).
Note typical worm-eaten appearance of fingernail destroyed by fungus.

when topicals can't.

Potent, systemic fungistat

GRISACTIN provides the antifungal activity needed to control tinea infections, including onychomycosis, that invade the dermis and deeper regions. Systemic action penetrates where topical action often fails.

GRISACTIN is effective against a wide range of fungi: *Trichophyton rubrum, T. mentagrophytes, T. tonsurans, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum canis, M. audouini, M. gypseum,* and *Epidermophyton floccosum.*

Peak serum levels are usually produced in about four hours with a single 500 mg. tablet. To meet the requirements of different patients—depending on body weight, age, severity, and location of infection—dosage is easily individualized with 125 mg. and 250 mg. capsules, and 500 mg. tablets.

Grisactin® 500

BRAND OF

griseofulvin (microsize) TABLETS

BRIEF SUMMARY
(For full prescribing information, see package circular.)

Grisactin®
Brand of
Griseofulvin (microsize)

Indications: Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum audouini, M. canis, M. gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, candidiasis (moniliasis), histoplasmosis, actinomycosis, sporotrichosis, chromoblastomycosis, coccidioidomycosis, North American blastomycosis, cryptococcosis (torulosis), *Tinea versicolor,* nocardiosis.
Contraindications: This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin.
Warnings: *Prophylactic Usage*—Safety and efficacy of griseofulvin for prophylaxis of fungal infections has not been established.
Animal Toxicology—Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in Pregnancy—The safety of this drug during pregnancy has not been established.
Animal Reproduction Studies—It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
Precautions: Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from a species of Penicillium, the possibility of cross-sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
Adverse Reactions: When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
Dosage and Administration: Accurate diagnosis of the infecting organism is essential. Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required, particularly in treatment of *tinea pedis.*
Dosage should be individualized, depending on age and severity of infection. *Adults*—0.5 Gm. daily (125 mg. q.i.d., 250 mg. b.i.d., or 500 mg./day). *Children*—10 mg./kg. daily is usually adequate (from 30 to 50 lb., 125 mg. to 250 mg. daily; over 50 lb., 250 mg. to 500 mg. daily, in divided doses).
How Supplied: GRISACTIN [griseofulvin (microsize)]—No. 442—GRISACTIN 125, each capsule contains 125 mg., in bottles of 100 and 500. No. 443—GRISACTIN 250, each capsule contains 250 mg., in bottles of 100 and 500. No. 444—GRISACTIN 500, each tablet (scored) contains 500 mg., in bottles of 60.

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform®-Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone (iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo.
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment,* 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion,* 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream,* 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment,* 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

BETADINE® Skin Cleanser

Degerms as it cleanses

Patients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—particularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

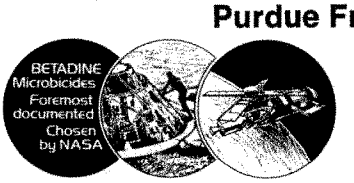
NORWALK, CONN. 06856 A8196 172076



The little book no mother should be without.

What? Buy another book on child-raising when you've already covered the subject from Spock to Salk?

What makes this little paperback different? It gives you in concise, capsule form what other books take pages of thumbing through and reading to give—authoritative answers to your questions on child-raising.

Published by the American Medical Association, GROWING PAINS is a quick reference guide to most of the questions you're likely to have about your child's physical, mental and emotional development and problems.

In it, respected pediatricians answer commonly asked questions about diet and eating habits, sibling relations, emotional problems, discipline and punishment, toilet training, speech disorders, sex education and dozens more.

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

SQUIBB® The Priceless Ingredient of every product is the honor and integrity of its maker.™

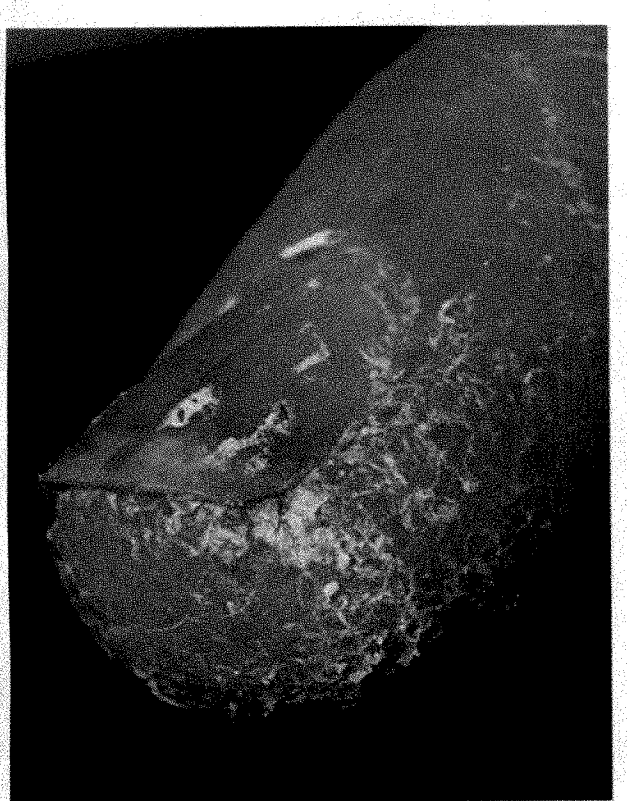
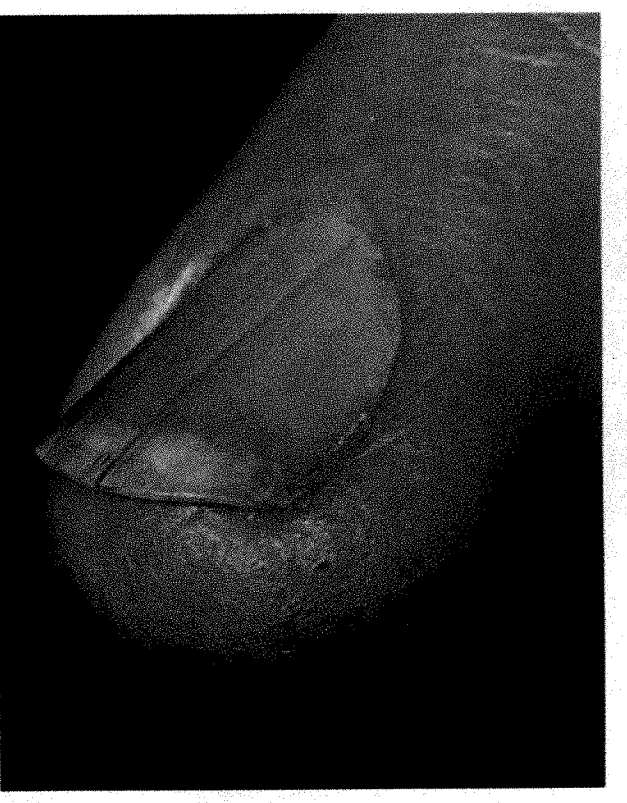
Pruritus relieved "within 24 hours"



Eczematoid Dermatitis

Condition of six months' duration. Patient complaining of acute itching and soreness of finger. Examination revealed erythematous, eroded, fissured, scaling and crusted dermatitis. KOH test negative for fungal hyphae; no other skin involvement or history of skin problems.



After 1 week

Halog 0.1% Cream applied twice daily. Patient reported pruritus relieved within 24 hours after first application of cream. Examination showed essentially complete resolution of dermatitis. Halog Cream discontinued and patient discharged.

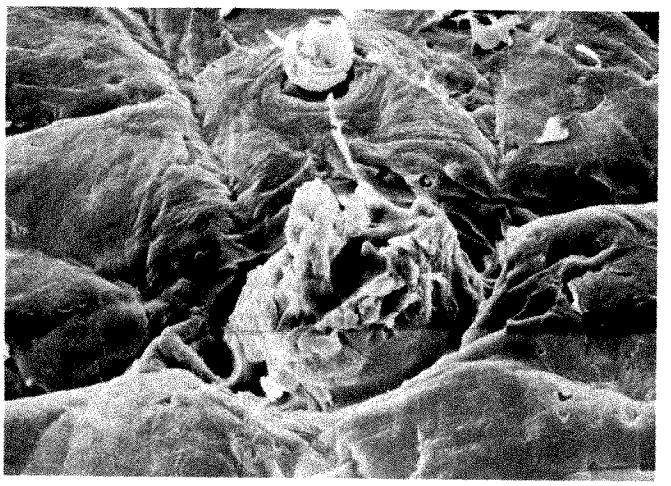
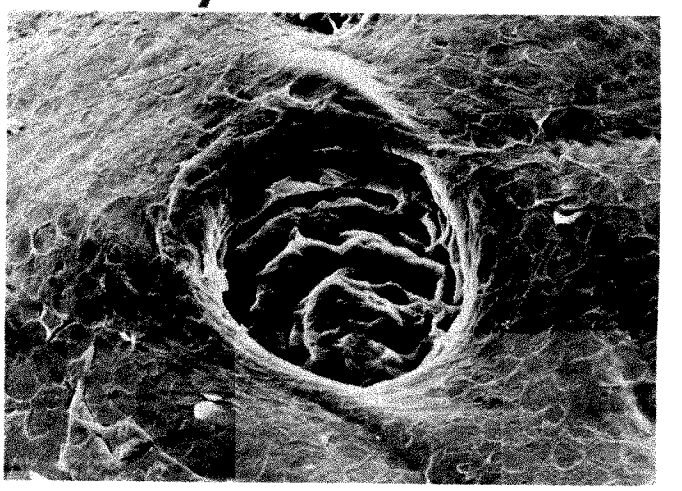
Pernox® Can Improve an Acne Lesion in Two Days



BEFORE TREATMENT: Comedo plugged with keratinous debris. (Scanning electron microscopy courtesy of Structure Probe Inc.)



AFTER 2 DAYS (Two one-minute Pernox® Scrub washes daily): Depth of orifice indicates removal of plug in large central comedo.

When we formulated Pernox® Scrub, we had a goal in mind. Make it abradant . . . a harsh word, yet make it smooth for acne skin. Pernox accomplishes just that.

Washing varies from patient to patient. You determine the regimen by frequency of washing and the amount of water used during the wash.

Patients respond to Pernox rapidly, often noticing improvement after the first wash. The unique combination of ingredients in Pernox emulsifies oil and dries affected areas, contributing to this success.

Two pleasant forms, regular and lemon-scented scrub and lemon-scented lotion offer you a choice for your patients' therapy.

Pernox . . . an acne regimen formulated to give you more than you're now getting from your present acne scrub.

PERNOX®

Scrub/Lotion

Lathering Scrub Cleanser for Acne

Pernox Scrub, Regular and Lemon-Scented in 2 and 4 oz. plastic tubes.

New Lemon-Scented Pernox Lotion in 6 oz. bottles.

Unusual Variant of Lupus Erythematosus or Lichen Planus

Clinical, Histopathologic, and Immunofluorescent Studies

Robert W. Romero, MD; Lee T. Nesbitt, Jr, MD; Richard J. Reed, MD

• Eleven patients with a skin disorder in which clinical, histopathologic, and immunofluorescent findings showed overlap features of both lupus erythematosus (LE) and lichen planus (LP) were observed for several years.

Clinical lesions were extremely long-term and consisted primarily of livid red to violaceous atrophic patches and plaques, most common on acral aspects of the extremities. Nails were also commonly involved, often showing anonychia.

Histologic changes combined cell-rich and cell-poor lichenoid patterns in the papillary dermis, suggesting both LP and LE. The major immunofluorescent finding in all patients was the presence of ovoid bodies at the dermal-epidermal (D-E) junction and in the upper dermis. Most patients showed both a linear arrangement and a clustering pattern of these bodies. Four patients also had coexistant but poorly developed linear deposits of immunoglobulins and complement at the D-E junction.

(*Arch Dermatol* 113:741-748, 1977)

Lupus erythematosus (LE) and lichen planus (LP) are two disorders affecting the skin that usually have different clinical, histopathologic, and immunofluorescent patterns. In occasional patients, however, the features of these two diseases may overlap.[1] Immunofluorescent studies in cases of this type have been infrequent. This report deals with 11 patients in whom the clinical, histopathologic, and immunofluorescent features in cutaneous lesions show overlap features between LE and LP, which in most instances cannot be clearly differentiated.

MATERIALS AND METHODS

During the period of 1969 to 1976, a total of 11 patients with a chronic skin disorder combining features of both LE and LP were observed and followed up in the dermatology clinic at Charity Hospital of Louisiana or the Veterans Administration Hospital in New Orleans. Clinical lesions from these patients were carefully studied and documented with photographs. Laboratory examinations were done to evaluate the patients for systemic LE.

Biopsy specimens from representative lesions were submitted for routine histopathology and direct immunofluorescent studies. Most patients had several biopsies for both types of examinations. Normal uninvolved skin was also taken from each patient for direct immunofluorescence.

For immunofluorescence studies, each specimen was immediately frozen in liquid nitrogen or placed in a recently described fixative solution.[2] Sections were cut at −20 C, placed on glass slides, and stained by fluorescent techniques previously described.[3] Conjugates consisted of commercially available lyophilized fluorescein-conjugated antihuman IgG, IgM, IgA, B_1C-B_1A (C3), and fibrinogen diluted 1:20, 1:5, 1:10, 1:5, and 1:2, respectively, with buffered saline and with fluorescein to protein ratios of 3.0, 3.3, 2.8, 2.3, and 2.8, respectively.

Clinical, Histopathologic, and Immunofluorescent Features of 11 Study Patients

Case/Race/Sex/Age, yr	Duration, yr	Clinical Features	Histopathology	Immunofluorescence
1/B/F/41	16	Livid red to violet atrophic ulcerative patches with telangiectasia and bullae: acral extremities, trunk, face, nails	Cell-rich & cell-poor patterns equally admixed; band-like infiltrate in some specimens with thickened basement membrane & liquefaction degeneration in others; numerous colloid bodies	Ovoid bodies: IgG, IgM; ANA negative*
2/B/M/49	21	Verrucoid atrophic erythematous to violaceous plaques with telangiectasia: palms, soles, dorsal hands, and feet, nails, trunk, penis	Cell-rich & cell-poor patterns admixed; thickened basement membrane in some & lichenoid cell-rich response in others	Ovoid bodies: IgG, IgM, C3; linear band on one occasion: IgG, IgM; ANA negative
3/B/F/72	2	Erythematous atrophic patches with hypopigmentation & hyperpigmentation & telangiectasia: face	Cell-rich pattern predominant but atrophy & follicular plugging in some areas.	Ovoid bodies: IgG, IgM, C3; ANA positive: 1:80; speckled
4/B/F/45	3	Atrophy & telangiectasia of proximal nail folds & nailbeds with loss of nail plates: nails only	Cell-rich pattern predominant with liquefaction degeneration & necrosis of keratinocytes, but basement membrane thickening & basal layer hypertrophy in others	Ovoid bodies: IgG, IgM; ANA negative
5/B/F/40	3	Atrophic erythematous to violaceous patches with hypopigmentation of distal phalanges & nailbeds & loss of nail plates; lower lip & oral mucosa also involved	Cell-rich pattern predominant, but with atrophy, liquefaction degeneration, telangiectasia, & numerous plasma cells	Ovoid bodies: IgG, IgM, C3; ANA negative
6/B/M/46	20	Erythematous atrophic areas with poikiloderma, mild follicular plugging, & nail dystrophy: nails, extremities, lip, face, scalp; oral mucosa also involved	Cell-rich & cell-poor patterns equally admixed with band-like infiltrate in some areas, & basement membrane thickening with few cells in others	Ovoid bodies: IgG, IgM, C3; ANA positive: 1:40; homogeneous
7/W/M/23	15	Atrophic, erythematous areas with hypopigmentation, telangiectasia, & anonychia: nail beds only	Cell-rich pattern predominant, but with atrophy, hyperkeratosis, & basement membrane thickening in several areas; numerous plasma cells	Ovoid bodies: IgG; ANA negative
8/W/M/58	7	Atrophic erythematous to violaceous areas with hypopigmentation, telangiectasia, scaling: dorsal hands, fingers, nails, extremities, neck	Cell-poor pattern predominant with thickened basement membrane, dermal fibrosis, & telangiectasia	Ovoid bodies: IgG; linear band on one occasion: IgG, IgM, C3; ANA negative
9/B/F/44	16	Erythematous atrophic plaques: arms, face, trunk	Cell-poor pattern predominant, but with cell-rich in some areas of papillary dermis & in perifollicular connective tissue	Ovoid bodies: IgM; linear band on one occasion: IgG, IgM, C3; ANA positive: 1:40; homogeneous
10/W/M/63	15	Atrophic violaceous to erythematous scaling plaques: dorsal hands, proximal nail folds, fingers, face, scalp	Cell-rich & cell-poor patterns admixed with smudgy basement membrane & thickening of blood vessel walls	Ovoid bodies: IgG, IgM; linear band on one occasion: IgG, IgM, C3; ANA negative
11/B/M/63	1.5	Atrophic violaceous scaling, plaques: face	Cell-rich pattern predominant, but with some areas showing thickened basement membrane	Ovoid bodies: IgG, IgM, C3; ANA negative

*ANA signifies antinuclear antibody.

CLINICAL FINDINGS

Clinical features are summarized in the Table. The lesions most commonly represented were large circumscribed atrophic patches and plaques with hypopigmentation and a livid red to blue-violet color, mild hyperpigmentation at the borders, minimal silvery scaling, fine telangiectasia, and a very thin epithelium that occasionally tended toward ulceration (Fig 1). Transient bullae occasionally occurred over a few lesions and some lesions developed a verrucoid surface. Follicular plugging was seem minimally in only two of these patients, and small lichenoid flattopped papules were not seen in any patients. Lesions tended to be fixed and stationary, and were generally poorly responsive to therapy, which consisted of topical and intralesional corticosteroids and systemic medications in a few patients, including corticosteroids, antimalarials, and immunosuppressive drugs. Pruritus was uncommon, but pain and tenderness were seen in lesions from some patients. Photosensitivity was not usually noted.

Lesions were most prominent on

the extremities, especially over acral aspects of extensor surfaces. Involvement of the skin of the distal phalanges and proximal nail fold areas with atrophy, severe nail dystrophy, and loss of some nail plates occurred in six cases (Fig 2). Palm and sole involvement was rather common (Fig 3). Lesions occurred on the face or trunk in some patients, but much less commonly and less extensive than on the extremities. Scalp involvement was seen in only two of our patients. Oral mucosal lesions, consisting of whitish to erythematous, slightly reticulated patches, occurred in two patients.

The disease process was notoriously chronic, having lasted for as many as 20 years in these patients with persistence of active lesions. There was an absence of clinical and laboratory evidence of systemic LE in most patients, with only three having low titer antinuclear antibody examinations and otherwise negative workup results for systemic LE. One patient (case 1) had coexistent rheumatoid arthritis with a very high titer rheumatoid factor. Systemic corticosteroids and immunosuppressive drugs were used to treat this patient, but gold therapy was never employed. Another patient (case 2) developed a deeply infiltrating squamous cell carcinoma of the sole of the foot on previously involved atrophic skin that eventuated in metastasis and death.

Fig 1.—Large atrophic lesions of hands with livid red to blue-violet color and tendency toward ulceration (case 1).

Fig 2.—Atrophy of nail beds and anonychia (Case 7).

Histopathology

In this discussion, lichenoid reaction is defined histologically as an inflammatory process that closely follows and extends across a basement membrane to produce lysis and destruction of epithelial cells.[4,5] This definition includes two basic patterns of lichenoid reactions pertinent in our cases, one of which is typified by the reaction seen usually in LP and the other by the reaction seen usually in LE.[5,6] In the former, the lichenoid pattern is substantially cellular, with lysis and dissolution of keratinocytes apparently mediated by aggressive lymphocytes. In the latter type, the histologic evidence for a role by aggressive lymphocytes migrating into the epidermis is meager, and lymphocytes do not comingle with keratinocytes in areas of their lysis and destruction. In the papillary dermal cell-rich variant (LP type), the dermal infiltrates are characteristically band-like, hug the epidermis, and extend across the basement membrane to attack keratinocytes. In the papillary dermal cell-poor variant (LE type), infiltrates tend to be perivascular in distribution, often

Fig 3.—Atrophic, hypopigmented lesions of palm with surrounding hyperpigmentation (case 6).

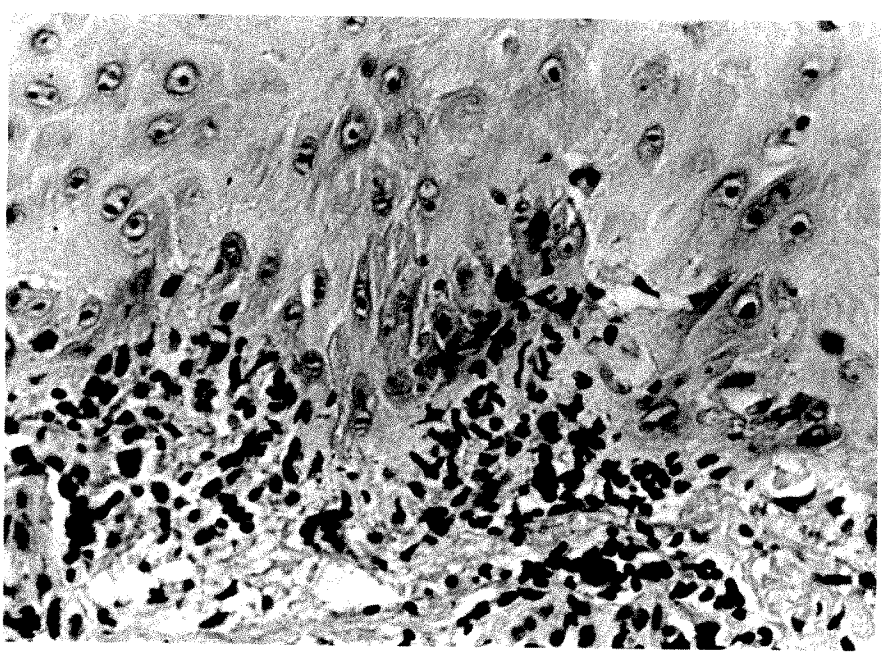

Fig 4.—Band-like lymphocytic infiltrate (cell-rich) that focally lyses basal keratinocytes and collects in irregular epidermal clefts (case 11) (hematoxylin-eosin, original magnification ×250).

are most prominent in perivascular areas of the reticular dermis, are spotty in the papillary dermis, and are loosely aggregated at the dermal-epidermal (D-E) junction. In some examples of LE, the thickened basement membrane appears to function as a barrier that confines infiltrates to the dermis and limits their migration into the epidermis.

In our 11 cases, both patterns are often represented in a single specimen, or multiple specimens from a single patient often show one or the other pattern. In these cases, the histologic differentiation between LP or LE is difficult. Major histologic features of each patient are summarized in the Table.

In five patients, the histologic pattern is predominantly a cell-rich response (Fig 4). Infiltrates of lymphocytes and histiocytes in the papillary dermis are band-like, hug the epidermis, and migrate across the basement membrane. The migrating lymphocytes concentrate in basal epidermal clefts and intermingle with clusters of necrotic keratinocytes (Fig 5). In spotty areas of some biopsy specimens, the epidermis shows mild liquefaction degeneration at the D-E junction but contains a loose infiltrate of lymphocytes. The epidermis usually is hyperplastic with compact hyperkeratosis and a prominent granular layer. In some lesions, the cell-rich pattern alternates with areas in which inflammatory cells are loosely aggregated in a widened fibrotic papillary dermis (Fig 6). In an occasional patient, multiple biopsy specimens have shown either a cell-rich pattern or a pattern of papillary dermal fibrosis.

In two patients, the biopsy material shows a predominant cell-poor pattern in the papillary dermis (Fig 7). The rete ridges are effaced and the basement membrane is often thickened. Vacuoles are distributed on both sides of the basement membrane. Lymphocytes are perivascular and loosely infiltrate the papillary dermis to cluster on the dermal side of the basement membrane. Lymphocytic infiltrates often are diffuse in the perifollicular sheaths and hug the follicles.

In four patients, the cell-poor and cell-rich patterns are admixed so that one pattern cannot be called predominant (Fig 8). Even in the two cases with a cell-poor pattern and in the five cases with a cell-rich pattern, there are commonly small foci in which the predominant pattern gives way to its counterpart, or several biopsy spec-

imens from different lesions in these patients show the opposite pattern in at least one specimen.

In addition to lymphocytes, plasma cells are a feature of the infiltrates in some of our specimens. These cells are found primarily in cell-rich reactions in our cases. Eosinophils are also seen in some of the dermal infiltrates in our patients.

In two cases, mucous membrane (oral) lesions had biopsies performed. In this material, the reaction is cell rich and contains numerous plasma cells.

Immunofluorescence

The Table also summarizes the immunofluorescent results. All 11 patients demonstrate deposits of IgG, IgM, and C3 in the form of fluorescent subepidermal ovoid or globular bodies on direct immunofluorescence of involved skin. These bodies are the major immunofluorescent finding in all specimens, and are found along the D-E junction zone and in the dermis, primarily in the papillary dermis, but occasionally extending into the upper third of the reticular dermis. The bodies are sharply defined, and are oval, round, or irregular in shape. In some specimens, the bodies have a greater tendency to hug the D-E junction zone (Fig 9), while in other specimens they are found primarily in aggregates or clusters extending well into the dermis (Fig 10 and 11). Both these patterns, however, are combined in several specimens, and multiple biopsy sections from the same patient often disclose one or the opposite pattern from specimen to specimen.

In addition to ovoid bodies, a coexistent but less prominent thin linear granular band of immunoglobulins and C3 is present along the D-E junction zone of involved skin in one of the biopsy specimens taken from four patients, but in specimens from other lesions in the same patients, only ovoid bodies without the presence of a linear band are noted. The four specimens with a fluorescent band suggest that feature seen usually in LE, but the linear deposits are poorly developed. Linear deposition of fibrinogen at the D-E zone, often seen in both LP and LE, is also present in many of the

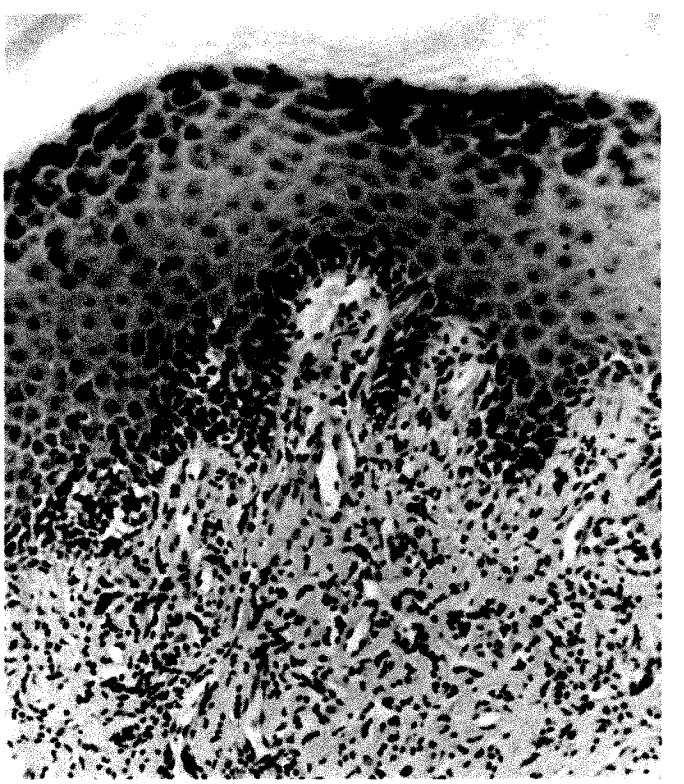

Fig 6.—Cell-rich lichenoid pattern with widened and fibrotic papillary dermis (case 4), (hematoxylin-eosin, original magnification ×120).

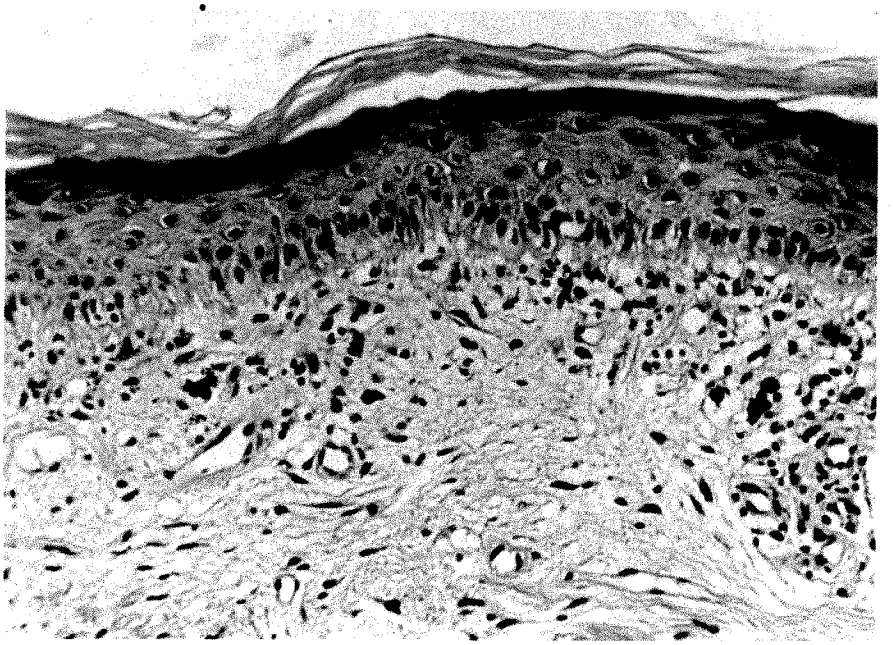

Fig 7.—Cell-poor pattern of lymphocytes confined to vascular adventitia and dermal side of basement membrane, which is thickened with vacuoles with tortuous capillaries (case 8) (hematoxylin-eosin, original magnification ×160).

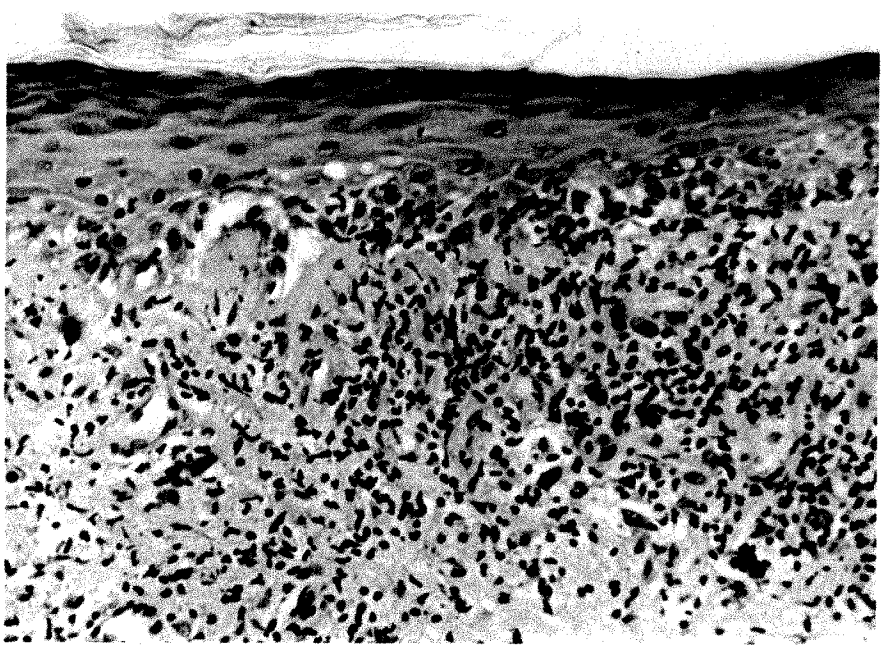

Fig 8.—Cell-rich lichenoid reaction (right) with effacement of rete and thickened basement membrane (left) more characteristic of cell-poor lichenoid pattern (case 6) (hematoxylin-eosin, original magnification ×160).

patients' skin lesions (Fig 12). Fluorescence confined to blood vessel walls or in a perivascular location is not noted in any of our biopsy specimens.

Normal uninvolved skin biopsy sections from each patient did not demonstrate deposition of immunoglobulins or C3 at any sites in any of the 11 patients.

COMMENT

The 11 patients in this report demonstrate a disease process with clinical, histopathologic, and immunofluorescent features suggesting both LE and LP, but in which a definitive diagnosis of one or the other disease cannot be made with certainty.

Clinical lesions in our patients were not diagnostic. Lichenoid flattopped papules typical of LP were not present. Follicular plugging and scalp involvement typical of LE were seen minimally in only two patients. Photosensitivity or pruritus was rarely a feature of our patients' skin lesions. Instead, the lesions tended to be most prominent on acral aspects of extensor surfaces of the extremities, and were characterized by livid red to violaceous atrophic patches and plaques. Nail involvement was commonly seen, as was involvement of the palms and soles. Lesions were extremely long-term, and generally responded poorly to most local and systemic treatment.

Histologically, LP and LE can commonly be separated on the basis of the concentration of lymphocytes in areas of keratinocyte damage.[6] In LP, the epidermis in sites of damage is heavily infiltrated with lymphocytes, and lysis of keratinocytes commonly produces clefts at the D-E junction zone. In LE, vacuoles form on both sides of a thickened basement membrane. They distort neighboring cells but seldom form clefts. Basement membrane thickening is a feature favoring a diagnosis of LE. Hyaline or colloid bodies can be seen in both LP and LE, but are usually more numerous and more compactly aggregated in LP. Two types of hyaline bodies have been identified[7]: (1) those of epidermal cell origin that can be shown to originate from degeneration of keratinocytes and that may be found in the epidermis and dermis, and (2) those originating from or continuous with thickened basement membrane that are found only along the D-E junction and in the uppermost dermis. Hyaline bodies of the first type occur in LP, but both types can be found in LE.[7]

Our patients show admixed features of cell-rich and cell-poor lichenoid patterns in the papillary dermis. There is variability in hyperkeratosis, acanthosis, epidermal atrophy, and

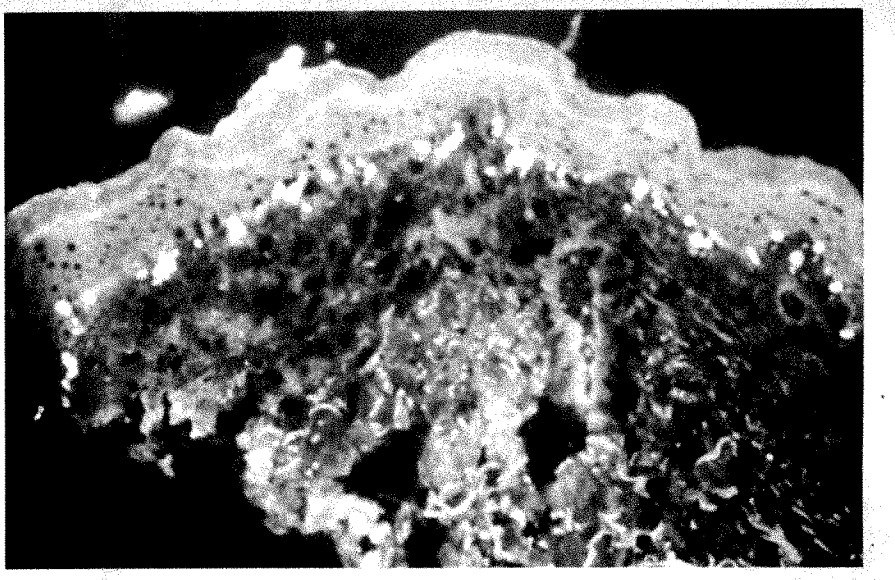

Fig 9.—Direct immunofluorescent specimen showing ovoid bodies in linear arrangement along dermal-epidermal junction suggesting lupus erythematosus pattern (case 3) (antihuman IgG staining, original magnification ×100).

follicular changes. Variability from specimen to specimen is also noted in degree of liquefaction degeneration of the basal layer, hyaline thickening of the basement membrane, and number of hyaline bodies present, with biopsy specimens from each patient more suggestive of LP in some instances and LE in others.

Certain histologic changes are seen in some specimens in our patients that are somewhat unusual for both LP and LE. These include a tendency toward papillary dermal fibrosis and increased numbers of plasma cells in the dermal infiltrates, both of which might be related to the chronicity and tendency toward ulceration of some lesions. Eosinophils are also seen in some of the dermal infiltrates, and have even caused us to consider lichenoid drug reactions in the histologic differential diagnosis.

Direct immunofluorescence of skin lesion biopsy specimens can commonly be used to separate typical cases of LE from LP. The LE lesions usually show a granular band of immunoglobulins and complement components in a linear pattern along the D-E junction,[8-10] and LP lesions almost always show fluorescent ovoid bodies in the D-E junction region and in the dermis.[11-13] Some LE lesions, however, may also show ovoid bodies alone or in conjunction with linear basement membrane fluorescence,[7,10,14] and LP lesions in one study showed linear D-E junction immunoglobulin and complement deposits in addition to fluorescent bodies.[13] In our typical cutaneous LE specimens, approximately 5% have shown only fluorescent bodies without linear staining, and these have usually been in long-standing lesions. All classes of immunoglobulins, complement, and sometimes fibrinogen may be deposited on the ovoid bodies. They correspond in size, shape, and anatomic location to the hyaline bodies seen histologically in LP and LE,[7,12] but they can be appreciated as being more numerous by fluorescence mi-

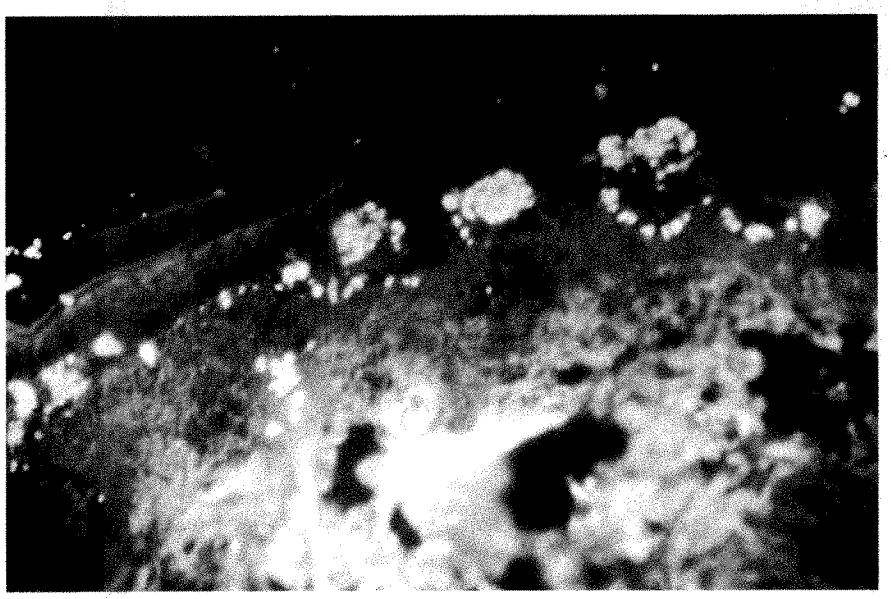

Fig 10.—Direct immunofluorescent specimen showing ovoid bodies in aggregates in papillary dermis suggesting lichen planus pattern, although some bodies show linear pattern (case 11) (antihuman IgM staining, original magnification ×100).

Fig 11.—Direct immunofluorescent specimen showing ovoid bodies in aggregates typical of lichen planus pattern (case 11) (antihuman IgM staining, original magnification ×450).

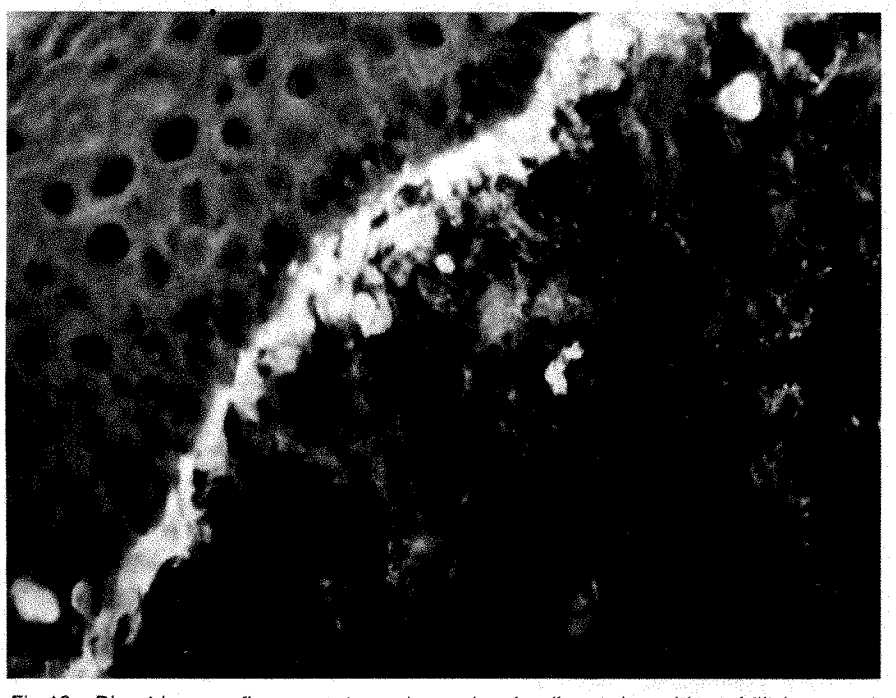

Fig 12.—Direct immunofluorescent specimen showing linear deposition of fibrinogen at dermal-epidermal junction zone (case 1) (antihuman fibrinogen staining, original magnification ×450).

croscopy. In LP, the bodies usually tend to cluster in large groups or aggregates, whereas in LE they tend to have a more linear arrangement along the D-E junction.[12] In our experience, fluorescent bodies in LP also usually attain greater depth into the dermis than those in LE. These bodies are not disease specific as they may be seen by immunofluorescence in smaller numbers in dermatomyositis and poikiloderma,[7,11,12] or in any disease process with appreciable destruction of epidermal keratinocytes or basement membrane material in which these substances become covered with immunoglobulins.

All of our patients demonstrate as their major immunopathologic finding the presence of fluorescent ovoid bodies at the D-E junction zone and in the dermis. In some instances there is more of a tendency toward clustering, and in others more of a linear arrangement, but often the pattern is mixed and different specimens from the same patient sometimes show opposite patterns. Four patients, on one of their immunofluorescent specimens, show a coexistent but poorly developed linear band of immunoglobulins and complement at the basement membrane zone in addition to ovoid bodies. This finding might suggest that LE is at least a part of the spectrum of these four patients' disease process. Linear deposits of fibrinogen, which may be seen at the D-E junction in both LE and LP,[12,13] are exhibited in several of our patients.

After having followed up this group of patients during many years, and having carefully studied their clinical findings and course, variable histopathologic features, and immunofluorescence, which does not completely settle the issue, we feel that these patients have a disease process in which LE or LP cannot definitely be diagnosed, and in which some of these patients may possibly have a coexistence of both diseases. Could it be that the Koebner reaction is doubly operative and synergistic in these patients?

This study was supported in part by a grant from the Veterans Administration.

Glucagonoma Syndrome

Report of Two Cases and Literature Review

Alan N. Binnick, MD; Steven K. Spencer, MD;
W. Landon Dennison, Jr, MD; Edward S. Horton, MD

• The glucagonoma syndrome is characterized by dermatitis, stomatitis, elevated serum glucagon levels, abnormal glucose tolerance, weight loss, and anemia—all in association with a glucagon-secreting alpha-cell tumor of the pancreas. A review of 21 cases showed strikingly similar features. A generalized, symmetrical dermatitis initially appeared to be asteatotic or eczematous over the perineum, buttocks, and lower extremities. Gradually, a more characteristic migratory necrolytic erythema with transient bulla formation and erosions developed in intertriginous and dependent areas. Histologically, the most specific features included necrolysis of the upper epidermis, with liquefaction necrosis of the granular cell layer and subcorneal clefting or blister formation. The dermatologist is often first to examine such patients; early recognition of this syndrome with prompt surgical removal of the primary pancreatic lesion may afford cure of the neoplasm.

(*Arch Dermatol* 113:749-754, 1977)

The dermatologist armed with a thorough knowledge of the cutaneous manifestations of systemic disease is in a unique position to clarify the true nature of an otherwise obscure clinical problem. When malignant neoplasms are involved, early diagnosis is essential.

Some cutaneous manifestations of internal malignant neoplasms, ie, pruritus ichthyosis, and urticaria, are not specific for malignant neoplasms alone. More specifically, the flush of the carcinoid syndrome, cutaneous Paget disease, and the rash of dermatomyositis may herald an underlying tumor. A relative newcomer now joins this list: the glucagonoma syndrome. Recently described, it consists of a glucagon-secreting alpha cell tumor of the pancreas associated clinically with characteristic dermatitis, weight loss, anemia, glucose intolerance, and sore tongue. The case reports of two patients are presented as examples to introduce a clinical review of this uncommon, but striking syndrome.

REPORT OF CASES

CASE 1.—A 58-year-old woman was noted to have a rash over her waist, buttocks, and extremities in 1973, when she was 56 years old. Increasing tiredness had developed and she had had a 5-kg weight loss in the previous six months. The dermatitis was accentuated on the inner thigh, perineum, and ankles, with symmetrical, crusted, scaling erythematous plaques and a few pustules. Potassium hydroxide examinations did not reveal fungal organisms. Several skin biopsy specimens were interpreted as nonspecific dermatitis, and the clinical differential included pemphigus variants, subcorneal pustular dermatosis, and impetiginized eczematous inflammation.

A sedimentation rate of 48 mm/hr and a normocytic normochromic anemia with a hemoglobin value of 10.8 gm/100 ml and a hematocrit reading of 33% accompanied by weight loss and tiredness prompted a search for malignant neoplasms. In March 1974, multiple tumor nodules, noted on liver scan, were delineated by celiac arteriography as a large, highly vascular mass in the right lower side of the liver, with scattered smaller nodules. A liver biopsy specimen was interpreted as probable hepatoma, with an unusual scirrhous pattern and only mild anaplasia.

She was treated from March 1974 until January 1976 with orally administered fluorouracil at a once weekly dosage of 500 to 700 mg. The rash, presumed to be related to hepatoma, persisted with a fluctuating course of flare-ups and improvement during treatment with topical lubrication, fluorinated corticosteroid creams, and intermittent wet dressings. Her general health, including her weight, remained stable.

It was apparent that the clinical course was not that of a hepatoma. She was again hospitalized in January 1976 to establish a diagnosis of glucagonoma syndrome, brought to our attention through a recent report.[1]

She appeared thin and pale. A generalized dermatitis involved her trunk and extremities. Crusted and eroded papules and plaques were most prominent on her buttocks, waist, and in the area where she wore a bra (Fig 1 to 2). Tender erythematous erosions and crusted plaques surrounded by brown hyperpigmentation were present in flexural areas and on the ankles and feet (Fig 3 to 4). Over the most erythematous areas on the dorsal part of the feet, there appeared to be superficial separation of the skin where bullae had formerly appeared. In lesions of one to two weeks' duration, hyperpigmentation and scaling developed, with a corresponding decrease in erythema and tenderness. The tongue was beefy with prominent furrows. A mild cheilitis was found to be normal on potassium hydroxide examination for fungus. The nails were friable and showed longitudinal ridging. A firm liver edge 2 cm below the right costal margin and a prominent hard small nodule in the inferior

Fig 2.—Accentuation of dermatitis on pressure area of buttocks.

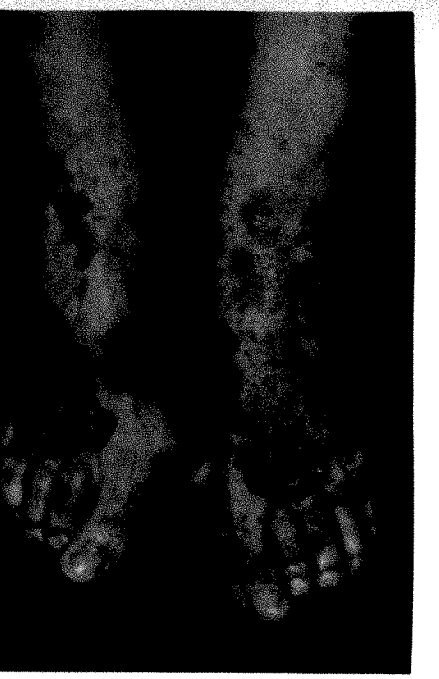

Fig 3.—Note irregular plaques with central erythema, crusting, and hyperpigmentation.

medial portion of the right lobe were palpated; the spleen was not felt. There was no lymphadenopathy and the remainder of the physical examination was normal.

Laboratory Data.—The hemoglobin level was 9.2 gm/100 ml and the hematocrit reading was 27.9%; the reticulocyte count was 1.4%. The serum vitamin B_{12}, folate, and iron determinations were normal. The erythrocyte sedimentation rate was 55 mm/hr. The serum cholesterol level was 125 mg/100 ml (normal, 135 to 270 mg/100 ml). A fasting serum insulin level was 30.5 μU/ml (normal, 6 to 26 μU/ml) and fasting gastrin 145 pg/ml (normal, 50 to 150 pg/ml). A three-hour glucose tolerance test revealed a fasting glucose of 95 mg/100 ml; at one hour, the value was 333 mg/100 ml; at two hours, the value was 353 mg/100 ml; and at three hours, the value was 193 mg/100 ml. Plasma amino acid values were greatly decreased. Test results were normal for urinalysis, blood urea nitrogen, serum creatinine, serum calcium, serum phosphorus, 24-hour urine 5-hydroxyindoleacetic acid, serum protein electrophoresis, and liver function enzymes.

The plasma glucagon determination was 6,750 pg/ml (normal, 100 to 200 pg/ml) fasting, and 8,500 pg/ml at the third hour of the glucose tolerance test. (Plasma glucagon was measured by radioimmunoassay using glucagon labeled with iodine 125 (^{125}I), antiglucagon antiserum 30K (Unger), and a double antibody separation method. Blood specimens were collected in an enzyme inhibitor, aprotinin, at 500 μ/ml, to retard degradation of glucagon by plasma enzymes.)

Fig 4.—Right foot. Bulla had been present on distal plaque several days before this photograph.

Celiac arteriography compared with studies performed two years previously showed an approximate doubling in size of the large, right hepatic lobe tumor mass. A small tumor "blush" was noted in the tail of the pancreas and was interpreted as the probable primary lesion (Fig 5).

Therapeutic measures such as systemic chemotherapy and surgery were not undertaken because of lack of definitive efficacy in published reports and because of the patient's relatively stable clinical course. A brief trial of zinc sulfate 220 mg orally three times a day was attempted because of the clinical resemblance of this dermatosis to acrodermatitis enteropathica; there was no improvement. The serum zinc level before this clinical trial was 96 μg/100 ml (normal, 80 to 165 μg/100 ml).

CASE 2.—A 52-year-old woman was first seen in February 1975, for sore mouth and a recurrent perineal rash. She had been well until August 1974 when she noticed a decrease in appetite, weight loss, and later menometrorrhagia. Two weeks after total abdominal hysterectomy for her pelvic symptoms, a sore mouth and dermatitis developed. Several cultures from the mouth and vagina yielded yeast organisms. She improved somewhat with oral and vaginal nystatin medication.

In May 1975, she was hospitalized with a widespread symmetrical eruption affecting the skin of the wrists, elbows, ankles, knees, clavicle, and the perioral and perianal areas. She was described as thin and appearing older than her 52 years. The rash consisted of reddish-brown patches with thin sheets of desquamating skin. The angles of her mouth were fissured and her tongue was bright red. The vulva was acutely inflammed, swollen, and covered with a serous exudate. The perineal dermatitis extended to the gluteal cleft. The margins of the eruption had hyperpigmented scaling with a few satellite pustules. Examination of the vagina showed slight inflammation and a yellow-brown discharge. There was no hepatosple-

nomegaly and the remainder of the physical examination was unremarkable. A skin biopsy specimen was interpreted as nonspecific dermatitis.

Laboratory Data.—The hemoglobin level was 10.8 gm/100 ml and the hematocrit reading was 35.1%; the leukocyte count was 7,500 (normal differential); the reticulocyte count was 1.4%. Values for serum total protein, albumin, calcium, and phosphorous were normal. A three-hour glucose tolerance test revealed a fasting glucose of 96 mg/100 ml; at one hour, the value was 242 mg/100 ml; at two hours, the value was 181 mg/100 ml; and at three hours, the value was 128 mg/100 ml. Plasma amino acid levels were greatly decreased.

Her appearance and examination findings suggested a nutritional or metabolic disorder. With wet compresses, topically administered corticosteroids, orally administered estrogen and multivitamins, she improved sufficiently to return home.

The possibility of glucagonoma syndrome was considered after review of a recent report.[1] A celiac arteriogram demonstrated a 10-cm tumor in the tail of the pancreas. At laparotomy in July 1975, the well-encapsulated tumor was removed by partial pancreatectomy, with no evidence of metastases found. Her preoperative plasma insulin value was 10 mcu/ml and plasma glucagon was 2,500 pg/ml. (Plasma glucagon was measured by radioimmunoassay using glucagon labeled with iodine 125, antiglucagon antiserum 30K (Unger), and a double antibody separation method. Blood specimens were collected in an enzyme inhibitor at 500 μ/ml to retard degradation of glucagon by plasma enzymes.) At surgery, the splenic arterial glucagon value was 2,800 pg/ml and the concentration of glucagon in a vein draining the tumor was 392,000 pg/ml. After surgery, her glucagon levels have ranged from 123 to 262 pg/ml. Electron microscopic examination of the tumor showed islet cells with a prevalence of alpha granules.

Two days after surgery, she noted that "her bottom didn't burn"; her dermatitis cleared during the next few weeks. Since surgery, she has gained weight with no evidence of tumor recurrence during 15 months of follow-up.

HISTOPATHOLOGICAL FINDINGS

Biopsy specimens were taken from the skin of the trunk and extremities of patient one and from the groin of patient two. Routine sections were stained with hematoxylin-eosin. The sections show alterations corresponding to those reported for glucagonoma syndrome.

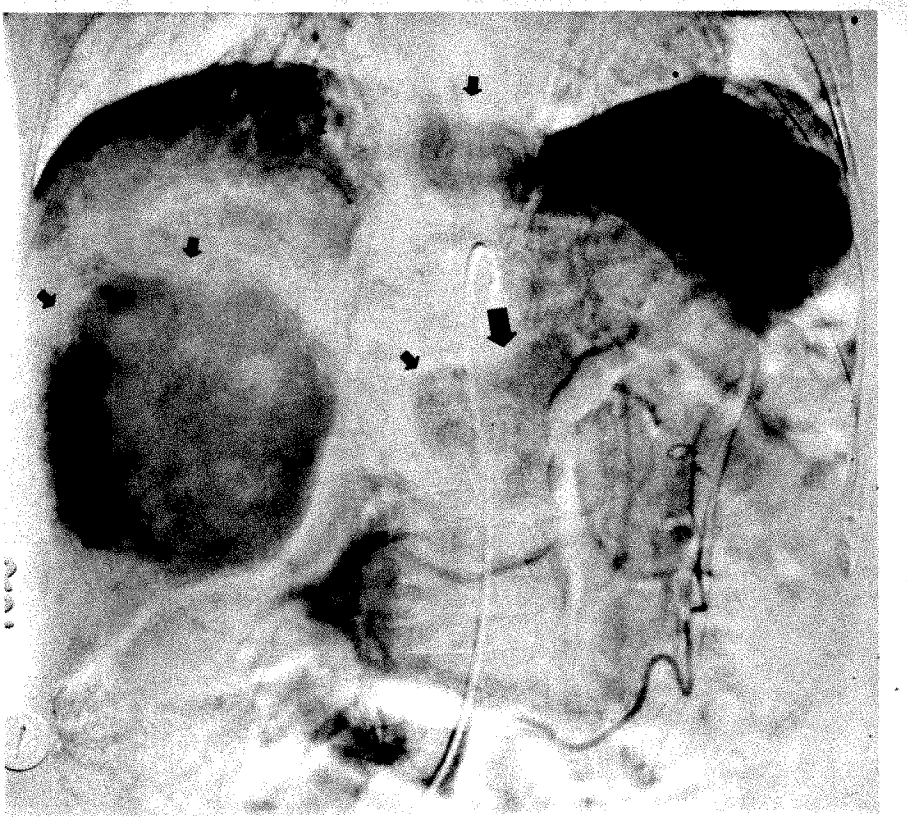

Fig 5.—Subtraction film of capillary phase celiac arteriogram. Note one large and multiple small vascular metastases within liver (small arrows). Large arrow points to vascular tumor in tail of pancreas

The most striking changes were in the epidermis, with spongiosis and necrosis in the upper layers of the stratum malpighii, with superficial cleft and bulla formation without acantholysis. A few sections showed hydropic degeneration in the subcorneal epidermis, with hypogranulosis and a few scattered dyskeratotic cells (Fig 6). Some sections showed psoriasiform hyperplasia with diminished or absent granular layer, parakeratosis, and clumps of bacteria. A mild perivascular upper dermal lymphocytic infiltrate was present. Immunofluorescent stains for immunoglobulin and complement (C3) deposition were negative.

HISTORICAL REVIEW

In 1942, Becker et al[2] reported the first case of what in retrospect was probably a glucagon-secreting islet cell tumor of the pancreas with associated characteristic dermatitis. Their patient had a widespread, symmetrical, scaly erythematous eruption, angular cheilitis, and glossitis. The clinical and histological description of the dermatitis was characteristic for that described in patients now known to have glucagonoma syndrome. A pancreatic neoplasm with histological islet cell features was found at postmortem examination.

McGavran et al[3] reported the first identified glucagon-secreting alpha-cell carcinoma of the pancreas in 1966. Their patient was described as having a bullous and eczematoid dermatitis of the hands, feet, and legs that defied specific diagnosis. The tumor contained alpha-cells and possessed increased glucagon-like activity.

Church and Crane[4] reported on a patient with migratory annular erythema combined with a superficial necrosis of the skin, glossitis, mild diabetes, weight loss, and normochromic anemia. Recognizing the similarities between their patient and that of Becker et al,[2] the authors had speculated that these symptoms and signs might indicate the presence of an islet cell carcinoma of the pancreas. At autopsy an islet cell pancreatic tumor was found.

Mallinson et al[5] published an exten-

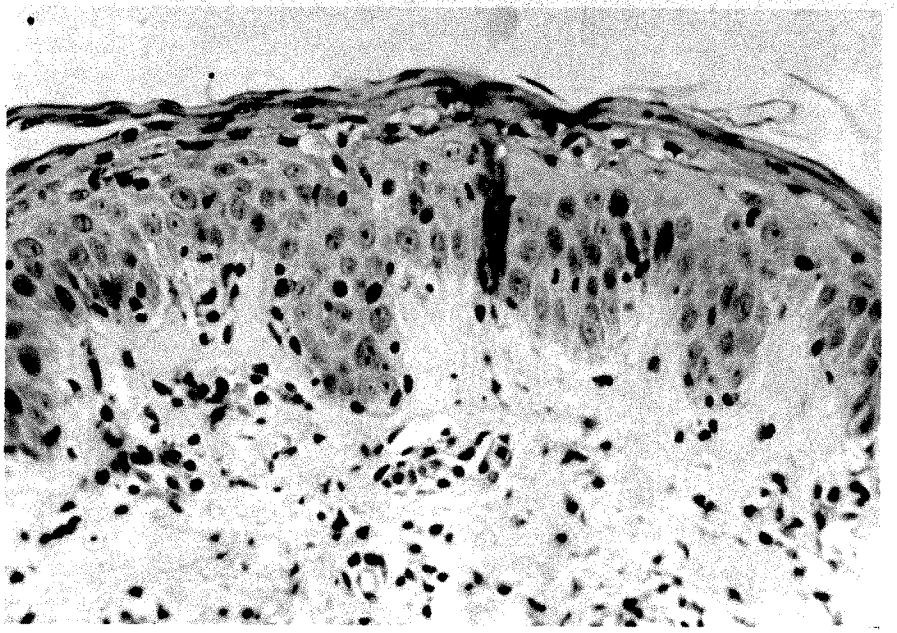

Fig 6.—This specimen shows characteristic absence of granular layer and hydropic degeneration in subcorneal epidermis (hematoxylin-eosin, original magnification ×100).

sive review on nine patients with the glucagonoma syndrome. Plasma amino acids were measured in four of these patients and most values were greatly lower than normal. The term necrolytic migratory erythema was first used by Wilkinson[6] to describe the rash clinically; the term superficial epidermal necrolysis was first used by Sweet[7] to describe the cutaneous histological process.

REVIEW OF CASES

Our two patients serve as classic examples of glucagonoma syndrome. Both patients had angiographically and pathologically verified islet cell pancreatic tumors, with greatly elevated plasma glucagon levels in association with dermatitis, stomatitis, weight loss, glucose intolerance, and anemia.

In reviewing the literature, we became aware of 19 other published case reports of the glucagonoma syndrome (Table). These cases were chosen for inclusion because of their characteristic clinical and pathological manifestations of the syndrome; in some instances, serum glucagon determinations had not been available at the time of presentation. There have been several other reports of patients possibly having the glucagonoma syndrome[8-10]; however, documentation was insufficient for inclusion in this review.

Skin lesions assumed one of two features. Often the initial dermatitis would suggest asteatotic eczematous dermatitis (eczema craquelé) with macular or barely palpable light-brown polygonal papules with slight superficial scaling. Unlike asteatotic dermatitis, this rash failed to respond to lubrication. The other pattern of dermatitis would begin as an erythematous area with gradual central blister formation progressing to central crusting and healing followed by hyperpigmentation 7 to 14 days after the initial erythema. This pattern was usually most severe on the perineum, buttocks, groin, lower abdomen, and lower extremities. Both patterns of dermatitis characteristically waxed and waned.

The clinical differential diagnosis of the dermatitis in the reported cases included Hailey-Hailey disease, pemphigus foliaceus, toxic epidermal necrolysis, subcorneal pustular dermatosis, acrodermatitis enteropathica, and generalized pustular psoriasis.

Many authors in early case reports stressed the nonspecificity of the skin biopsy specimens; however, if a biopsy of the early lesions is done, a rather characteristic histological picture like that described for our two patients may be seen. In several patients, direct immunofluorescence studies did not show any immunoglobulin or C3 complement deposits.

A beefy, sore tongue was present in 17 of the patients. Angular cheilitis was present in almost every patient. Occasionally, yeast organisms were identified from oral lesions. Nail dystrophy was a prominent feature in six patients.

In all of the patients examined for elevated levels of plasma glucagon, extremely high levels were found. Nineteen of the 21 patients had either elevated fasting blood glucose levels or glucose tolerance tests similar to those found in diabetic patients. In no instance was a positive family history of diabetes mentioned. No patient had any complications associated with diabetes. Normochromic normocytic anemia was present in the patients in 15 of the 16 case reports most recently reported. With one exception, weight loss was a consistent feature. Mallinson et al[5] excluded significant fat malabsorption in their patients. Serum cholesterol determination was mentioned in five case reports and in every instance was either low or low normal. The sedimentation rate varied from 30 to 100 mm/hr.

Liver metastases were noted in patients in more than half of the cases, local lymph node and spine involvement in two patients each, and metastases to the left adrenal gland in one patient. Because the head of the pancreas is rarely involved, jaundice is not a clinical feature.

There were 17 women and four men. Most of the patients were middle aged, with 16 of the 21 patients between 40 and 60 years old; only one patient was less than 40 years old (Table, case 20). It is difficult to determine survival rates from the limited number of case reports and from lack of follow-up data; however, the slow-growing nature of many malignant glucagonomas is apparent. In one series,[5] seven of nine patients had been symptomatic for two to 12 years. In four of the cases, the duration of symptoms was 5½ years or greater.

Our second case is the second reported patient to our knowledge in whom it was feasible to remove the primary lesion and therefore obtain a possible cure. In case 3 there has been

*Assay methods may not be comparable. Normal plasma glucagon usually listed as up to 100 to 200 pg/ml.
†Case 3 is also presented in Sweet,[7] Lightman and Bloom[38] and Warin[39]; case 4 in Wilkinson;[6] and cases 5 to 9, 11 in Warin.[39]

no evidence of tumor recurrence three years after removal of the tumor (Mallinson, personal communication, 1976). With respect to dermatitis, almost complete clearing occurred within two weeks in the two patients in whom the primary tumor was successfully removed. About half the remaining patients noted significant improvement of the dermatitis with the use of topical corticosteroids.

COMMENT

Glucagon, one long polypeptide chain of 29 amino acids, is produced in the alpha-cells of the pancreatic islets of Langerhans. Mild hyperglucagonemia has been reported in patients with physiological stimuli to glucagon secretion such as protein ingestion or starvation,[11,12] insulin withdrawal, diabetic ketoacidosis,[13] uremia,[14] cirrhosis of the liver,[15] Cushings syndrome,[16] acromegaly, pheochromocytoma, and acute pancreatitis.[17] Greatly elevated plasma glucagon levels have been reported only with alpha-cell tumors of the pancreas.

There have been five distinctive clinical syndromes associated with neoplasms of the islets of Langerhans[18]: glucagonoma, insulinoma, Zollinger-Ellison syndrome, carcinoid syndrome, and the watery diarrhea hypokalemic syndrome. Any of these tumors may occur as part of the syndrome of multiple endocrine adenomatosis, resulting in a mixed clinical syndrome caused by the secretion of more than one hormone.

To be considered a glucagonoma, a tumor must be shown to be secreting an excess of glucagon. To constitute the glucagonoma syndrome, we concluded that at least the characteristic dermatitis referred to as migratory necrolytic erythema must be present in addition to the hyperglucagonemia. Glossodynia, diabetes, or abnormal results from a glucose tolerance test, weight loss, normochromic normocytic anemia, elevated sedementation rate, and perhaps also hypocholesterolemia are other associated features. Although not previously reported as being a feature of the syndrome, hypocholesterolemia is not a surprising finding since it has been shown that glucagon administration will lower blood cholesterol levels.[19-21]

Once the diagnosis is established (or if there is a high index of suspicion), a celiac arteriogram should be performed to localize the primary lesion and possible metastases. More than 60% of islet cell tumors are demonstrated by arteriography[22] in contrast with adenocarcinomas of the pancreas for which arteriography is often not helpful. A liver scan should also be done because of the high incidence of liver metastases. Various screening tests for other endocrinopathies may be indicated since a glucagonoma may be part of multiple endocrine adenomatosis.

It is very difficult histologically to determine whether endocrine tumors (including glucagonoma) are benign or malignant. Metastases occurred in 13 of 21 patients (62%) with glucagonoma syndrome. By contrast, approximately 20% of insulinomas are malignant.[23]

Any attempts to understand the cause of the dermatitis in glucagonoma syndrome have been speculative to our knowledge to date. Infusion of glucagon will substantially diminish plasma amino acids[24]; in those patients with glucagonoma who were tested, plasma amino acid levels have been greatly decreased. Mallinson et al[5] speculated that the skin rash might be based on excessive catabolism perhaps mediated through the hypoaminoacidemia.

Dermatitis and normocytic anemia occur in protein malnutrition.[25] In acute cases of kwashiorkor, superficial bullae may occur and the skin appearance may resemble that of a burn. Within a week, regardless of treatment, desquamation may be noted and with recovery, hyperpigmenta-

tion is usually seen.[26] Henington et al[26] reported three patients with kwashiorkor, all of them had some features resembling the dermatitis associated with glucagonomas. The dermatitis seen in kwashiorkor may be related to hypoaminoacidemia, and skin lesions of kwashiorkor have been cured with vitamin-free casein or a mixture of pure amino acids.[27]

Patients with essential fatty acid deficiency have an associated dermatitis characterized by erythema with a dry and scaly appearance accentuated in intertriginous areas.[28-31] We are not aware of any studies concerning fatty acid determinations in patients with glucagonomas.

The distribution of the dermatitis suggests pressure and friction as being important. Although essentially any area of the body may have the dermatitis, the buttocks, perineum, lower legs, ankles, and feet seem to be involved most often. There seems to be an increased incidence of bacterial and yeast infections; this may simply be due to the loss of structural integrity of the epidermis.

Treatment of the dermatitis is difficult to evaluate because of the irregularity of its natural course. Topical corticosteroids seem to be helpful in controlling the dermatitis in many cases. Mallinson et al[5] found diiodohydroxyquin treatment helpful in two patients and orally administered tetracycline therapy helpful in another; dapsone (two patients) and niacinamide (one patient) did not help.

Surgical and chemotherapeutic approaches have been considered for treatment of the tumor itself. If there is no evidence of metastases at the time of presentation, as in our second case report, resection of the tumor may afford cure of the neoplasm. It is not known whether resection of either the primary neoplasm in the presence of metastatic lesions or resection of most of the tumor mass will affect the natural history of the malignant neoplasm.

Streptozocin, a nitrosourea chemotherapeutic agent, has been effective in treating patients with malignant tumors of beta-cell origin[32] and may be of value in treating glucagonomas. Patient 21 seems to have undergone a remission after streptozocin therapy, with a return of his circulating immunoreactive glucagon level to normal.

Becker et al[2] wrote that "...a comment on our first case seems to be impossible at present, and we restrict ourselves to the recording of it. Only the observation of other cases of pancreatic tumor will decide whether the cutaneous changes in our case were primarily due to the neoplasm." It is now clear that although the mechanism is unknown, rather specific and recognizable cutaneous changes accompany pancreatic glucagonomas.

Supported in part by Public Health Service grant MO1-RR-109 (Clinical Research Center), and Westwood Pharmaceuticals.

Robert F. Jeffery, MD, performed the celiac arteriogram in case 1.

Ultrastructural Studies of Vitiligo, Vogt-Koyanagi Syndrome, and Incontinentia Pigmenti Achromians

Masaaki Morohashi, MD, PhD; Ken Hashimoto, MD; Thomas F. Goodman, Jr, MD; Dennis E. Newton, MD; Toivo Rist, MD

• **Studies of early progressive vitiligo, Vogt-Koyanagi syndrome, and incontinentia pigmenti achromians were made by electron microscopy. At the periphery of the depigmented lesions, the melanocytes had several subcellular abnormalities, ie, vacuolization of the cytoplasm, aggregation of melanosomes, autophagic vacuoles, fatty degeneration, pyknosis or homogeneous cytoplasmic degeneration, and others. Numerous nerve endings were seen in close contact with the basal lamina of the epidermis or even within the epidermis. Direct continuities between Schwann cell basal lamina of nerve endings and the basal lamina of the melanocytes were observed. Nerve endings could be associated with either normal or abnormal melanocytes.**

(*Arch Dermatol* 113:755-766, 1977)

Regarding the mechanisms involved in melanocyte disappearance in several depigmenting skin disorders, there is no consensus of opinions. Transformation of melanocytes into Langerhans cells (L-cell) or related cells in vitiligo has been proposed by Birbeck et al[1] and the idea followed by other authors.[2-5] An autoimmune mechanism has been proposed by Copeman et al[6] as appearing in vitiligo with demonstration of antimelanocyte antibody, whereas Hashimoto[7,8] suggested that the peripheral nerve might play a role in halo nevus, since a number of nerve endings were demonstrated in the basal layer of the epidermis where melanocytes have disappeared. The neurogenic hypothesis of vitiligo was advanced by Lerner[9] and Chanco-Turner and Lerner[10]; it was based upon their physiologic observations that predominance of cholinergic influences such as increased sweating exists in vitiliginous skin.

The present work was undertaken to elucidate the mechanism of depigmentation in three depigmentary conditions: vitiligo, Vogt-Koyanagi syndrome, and incontinentia pigmenti achromians. Emphasis was placed on the nerve-melanocyte relationship in the process of depigmentation.

REPORT OF CASES

Vitiligo

Studies of three patients with vitiligo of recent onset were made. The biopsy specimens were removed from a white hair area of the left frontal scalp and from the cheek of a 40-year-old black man (Case 1), the right cheek of a 5-year-old black girl (Case 2), and the right shoulder of an 18-year-old black woman (Case 3).

Incontinentia Pigmenti Achromians

CASE 1.—A female patient was born (Nov 24, 1968) with thin white lines in the shape of a mirror image of an "S" on the frontal and lateral portions of her left chest and abdomen. During the next several years these lesions gradually extended both toward the medial side anteriorly and the midline posteriorly. Eventually, the verti-

Hypopigmented lesion (×40,000).

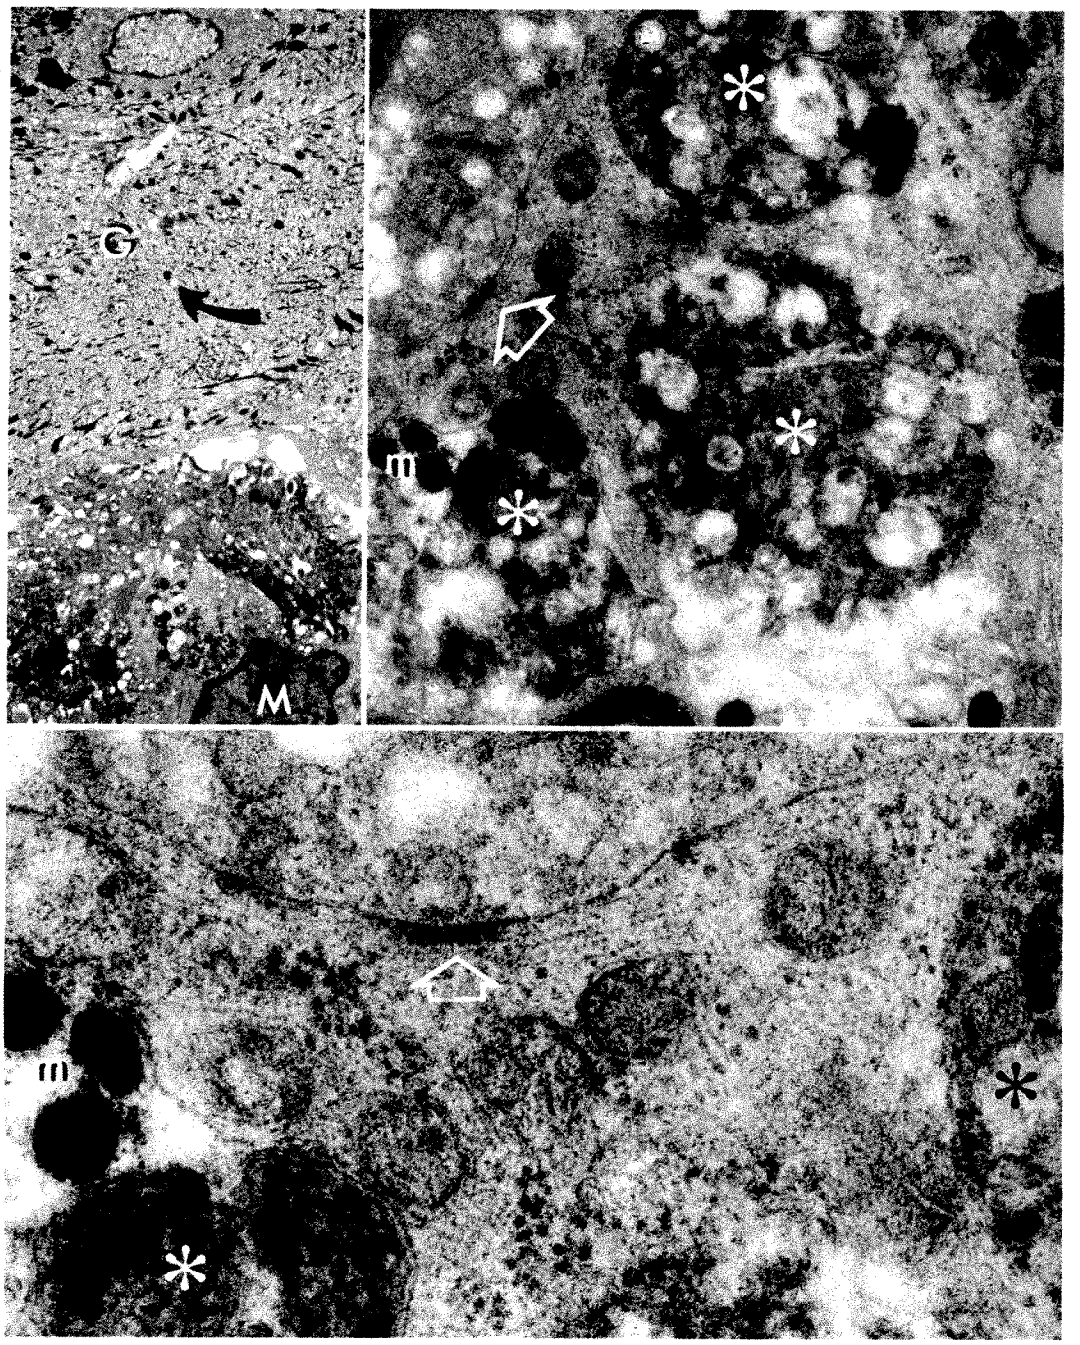

Fig 5.—Vitiligo (case 1). Top left, Low magnification of degenerated melanocyte (M) seen in high level of epidermis. Granular cells (G) containing keratohyaline granules (curved arrow) are just above degenerated melanocyte. Top right and bottom, Higher magnification is part of melanocyte; numerous autophagosomes (asterisks) digest their own melanosomes (m) and other organelles. Hollow arrows show hemidesmosomes of melanocyte. Hypopigmented lesion (top left: ×3,200; top right: ×32,000; bottom: ×80,000).

cal connections disappeared, leaving a series of three horizontal lines (Fig 1, top left and right and bottom left). At the age of 1½ years, an extremely thin hypopigmented line appeared from the perianal region of the left buttock down the posteriomedial thigh and leg to the ankle (Fig 1, bottom right). This also widened with time but to a much lesser extent than the trunk lesions. There has never been any paraesthesia or anesthesia in the area. The depigmented areas sunburned easily and have never shown any signs of tanning. She is a normally developed intelligent child.

No similar lesions were found in any other family members on either side of the family. The mother had many attacks of asthma and experienced mild hypertension. Medications for these conditions included antihistamines and phenobarbital. During her pregnancy there was no bleeding; no hormones were administered; and the delivery was normal.

The child has had several episodes of streptococcal sore throat and tonsillitis, as well as otitis media bilaterally and serous otitis media with some bilateral hearing loss.

CASE 2.—An 8-year-old black girl was admitted to the Pediatric Service, Medical College of Georgia, Eugene Talmadge Memorial Hospital, in December 1972, for evaluation of a seizure disorder. Because of large hypopigmented areas on her trunk that were present since birth (Fig 2), she was referred to the Department of Dermatology. A skin examination showed a bizarre streaking and whorling hypopigmented area on the right upper quadrant of both anterior and posterior thorax, extending slightly over the shoulder and neck.

She had had a mild febrile disease and headache one year prior to admission that was thought possibly to be viral meningitis. She had a five-month history of occasional episodes of eye blinking, progressing to a jerking of the head and right arm. No loss of consciousness occurred. These symptoms responded well to phenobarbital administration.

Results of a physical examination were normal except for increased deep tendon reflexes on the left side of the body.

Vogt-Koyanagi Syndrome

CASE 3.—A 42-year-old black woman came to Eugene Talmadge Memorial Hospital, Augusta, Ga, with one month's duration of loss of skin pigment, dysacusia, photophobia, decreased vision, and increased tearing, pain, burning, and itching of the eyes. The exact time relationship of the skin changes to the eye and ear symptoms was unclear to the patient. It is certain, however, that the skin changes preceded the eye and ear symptoms. Examination of the skin showed symmetrical loss of pigment of the face, shoulder, trunk, and extremities. A large confluent lesion was found over the shoulders. Results of an ocular examination showed her visual acuity to be profoundly decreased. There were 1+ aqueous cells and flare present bilaterally. On fundus examination, there was deep central cupping of the optic nerve head with nasal displacement of vessels. The retinal vessels appeared narrowed and arteriovenous nicking of a mild degree was noted. Macular edema was present. Circumferential bullous retinal detachments were noted bilaterally. An audiogram showed hearing loss that did not impair her ability to communicate.

The patient was treated in the hospital with 80 mg of prednisone daily for 12 days, and 40 mg of prednisone every other day for 6 days. At the end of this period, visual acuity had improved to 20/40 in the right eye and 20/50 in the left eye. Bullous retinal detachments remained unchanged bilaterally.

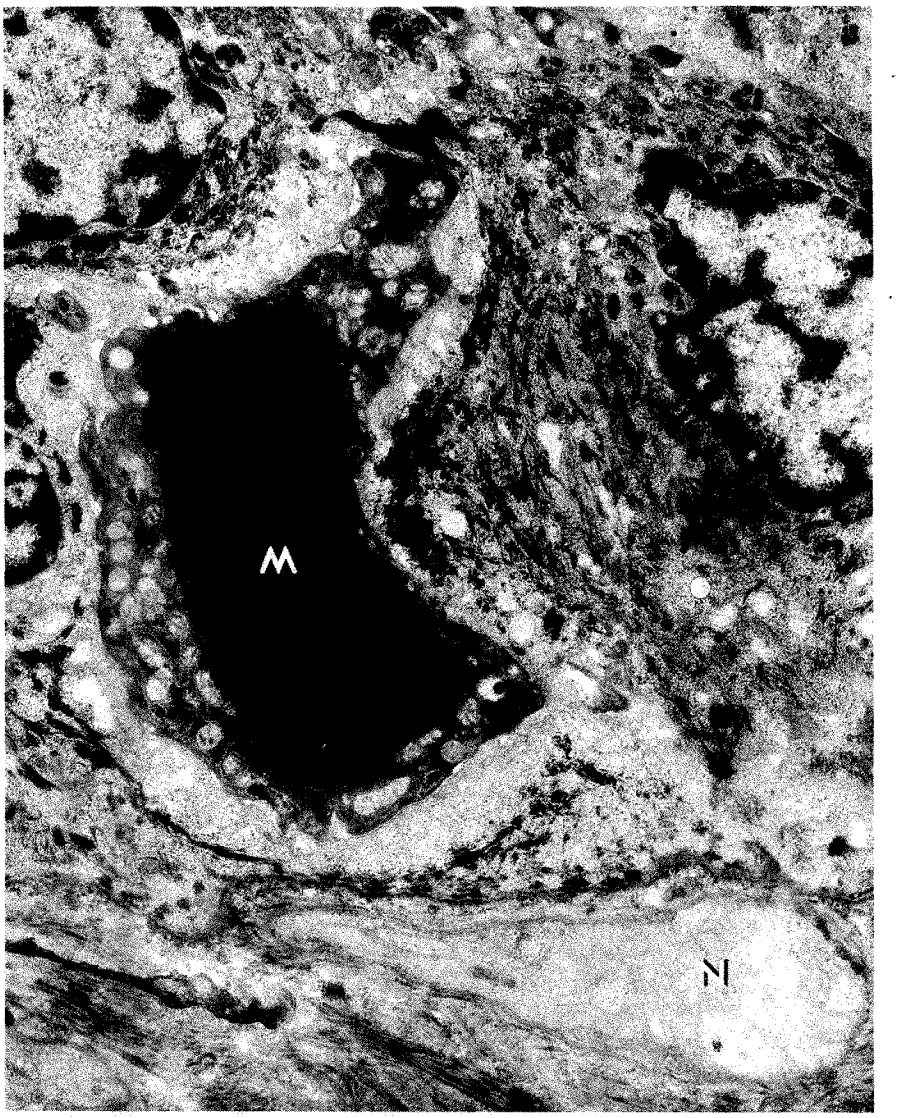

Fig 6.—Incontinentia pigmenti achromians (case 1). Melanocyte (M) shows pyknosis and homogeneous coagulation of cytoplasm. Note presence of nerve ending (N) seen close to degenerating melanocyte. Hypopigmented lesion (×8,000).

MATERIALS AND METHODS

In these depigmenting conditions the pigment loss in the lesion is usually not abrupt but gradual. In black patients there is a shade of gray between the depigmented center of the lesion and the normal skin. It was anticipated that there are gradients of pathologic changes if we

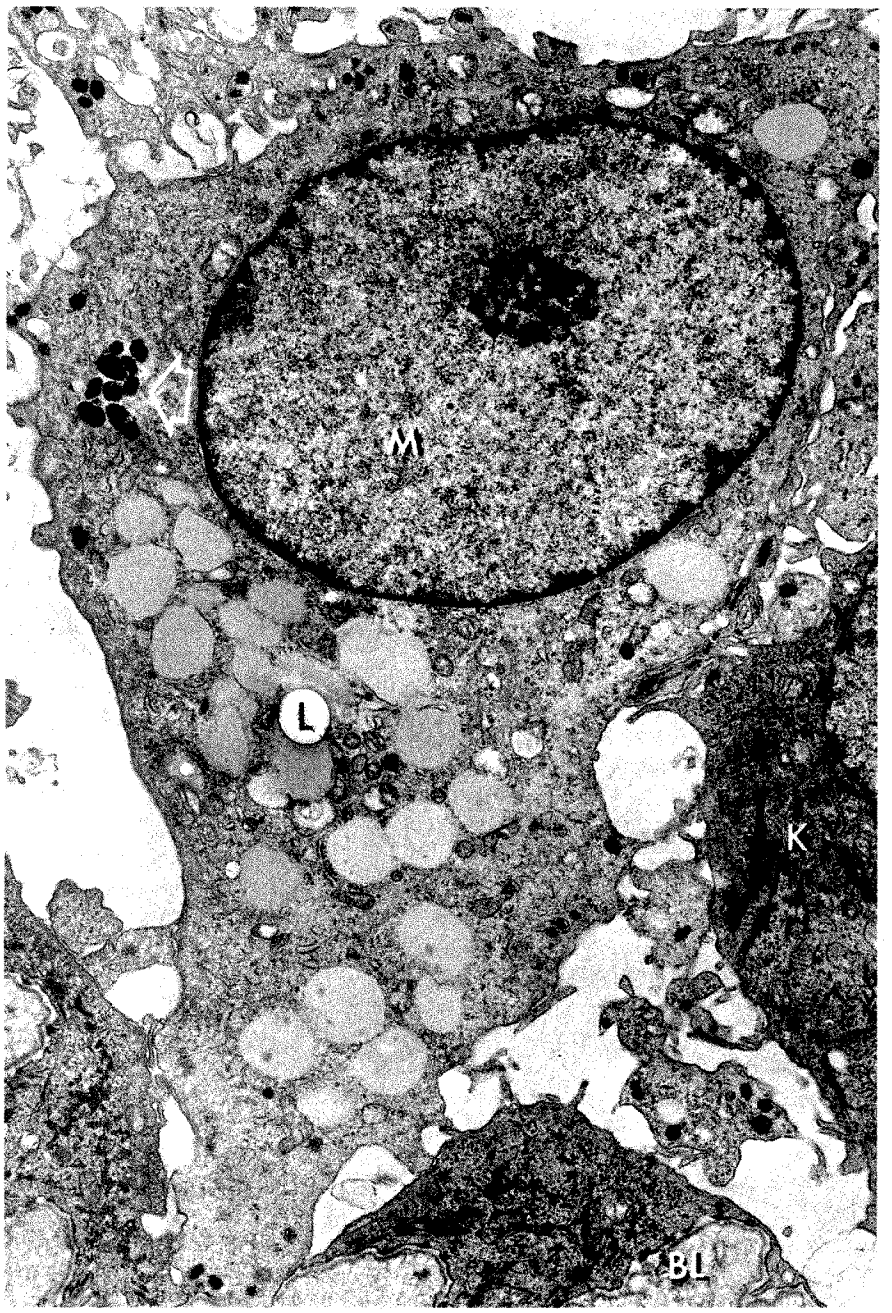

Fig 7.—Vitiligo (case 1). Melanocyte (M) shows fatty degeneration (L). Within cytoplasm of melanocyte, aggregation of melanosomes (hollow arrow) is seen. Basal lamina indicated by BL; K, keratinocyte. Hypopigmented lesion (×10,000).

examine three different areas in each specimen beginning from normally pigmented area, through an intermediate or hypopigmented area, and a completely depigmented area, usually located in the center of the lesion. In Fig 1 the biopsy scars show how this selection of biopsy sites was done in one lesion. Specimens were taken from the pigmented, hypopigmented, and depigmented areas of the lesion of three patients with vitiligo. Three specimens were obtained from the lesions of the left chest of case 1 of incontinentia pigmenti achromians; the center (depigmented), intermediate (hypopigmented), and peripheral (normal color) sites of the involved area (Fig 1, top right) had biopsy procedures. Normal skin was also taken from the right chest for a control. Specimens from case 2 of incontinentia pigmenti achromians were taken from the lesion on the right chest (Fig 2, left) in the same way (pigmented, hypopigmented, and depigmented areas) and from the left thigh to serve as a control. Each biopsy specimen of case 2 was further divided into two parts: one for histochemical studies of levodopa[11] and the other for electron microscopic examination. Biopsy specimens of Vogt-Koyanagi syndrome were performed in the same way (pigmented, hypopigmented, and depigmented areas) from the involved area of the left shoulder. All the biopsy specimens were taken with the patient under 1% procaine hydrochloride anesthesia.

All tissues for electron microscopic studies were immediately sliced into 1-cu mm blocks and fixed for three hours in 5% glutaraldehyde buffered to pH 7.4 with 0.1M cacodylate. After an overnight rinse in the same buffer, the tissue blocks were treated with 1% osmic acid in the same buffer for 30 minutes. Graded concentrations of ethanol (50% through absolute) and propylene oxide were used for dehydration; epoxy casting resin A was used for embedding the specimens. Thick sections were cut at 1 μ from each block and stained with 0.01% azure B on a hot plate. Thin sections were cut at 400 to 600 A in an ultramicrotome and stained with 15% uranyl acetate in 100% methanol and then with lead citrate.[12] Stained sections were observed in an electron microscope.

RESULTS

In case 2 of incontinentia pigmenti achromians, levodopa-reactive melanocytes were less abundant in the hypopigmented lesion than in the pigmented control skin (Fig 3, left and right).

The electron microscopic findings in

vitiligo, Vogt-Koyanagi syndrome, and incontinentia pigmenti achromians were almost identical (see Tables 1 and 2); the following descriptions, therefore, apply to all three depigmentary conditions.

In the depigmented area (the center of the lesion), no melanocytes were present and melanosomes in the keratinocytes were substantially decreased in number or absent. Most of the nonmelanocytic clear cells in the lesion of vitiligo and Vogt-Koyanagi syndrome were L-cells containing characteristic granules. In incontinentia pigmenti achromians, however, numerous cells that did not contain either melanosomes or L-cell granules were seen in the basal layers. Most of them were considered to be melanocytes since they were attached to the basal lamina with hemidesmosomes[13-15] (cf, Fig 4 and 5, bottom). At the epidermal-dermal junction, nerve endings were frequently observed.

In both the hypopigmented and the pigmented areas (the periphery of the lesion), many melanocytes had multiple abnormalities, ie, vacuolization of cytoplasm (Fig 6), fatty degeneration (Fig 7), autophagic vacuoles (Fig 4 and 8, bottom right), aggregation of melanosomes (Fig 7 and 9), and others (see Table 2). These abnormalities were present to a different degree in each cell. Degenerating melanocytes seen in the high level of the epidermis showed in their cytoplasm numerous autophagosomes at various stages of digestion (Fig 5, top right and left and bottom). A small number of melanocytes, however, showed no apparent sign of degeneration. Most of those in incontinentia pigmenti achromians showed a decrease in the number and size of their melanosomes. The L-cells found in the vicinity of these degenerating melanocytes appeared normal. No mitotic melanocyte or L-cell was found. Some basal keratinocytes surrounding the degenerated melanocytes showed mitosis (Fig 9).

Numerous nerve endings were seen in close contact with the basal lamina of the epidermis or even within the epidermis in both the hypopigmented and the pigmented areas of the lesion (Fig 4, 6, 8, 10, 11, top and bottom, and 12). These nerve endings were mostly associated with both normal (Fig 8, 10, and 11) and degenerated (Fig 4, 8, and 6) melanocytes of the basal layer of the epidermis. After serial sectioning, many nerve endings, which apparently were not associated with melanocytes in the first section, could be traced to the melanocytes or their dendritic processes. They consisted of one or more axons surrounded by small Schwann cell processes. Most of the axons were typical in that they contained many mitochondria, neurotubules, and small vesicles (Fig 4, 11, and 12, inset). Dense bodies, multivesicular bodies, and glycogen granules were also seen in various numbers. Direct continuities between Schwann cell basal lamina of nerve endings and the basal lamina of the melanocytes were observed (Fig 8 and 10).

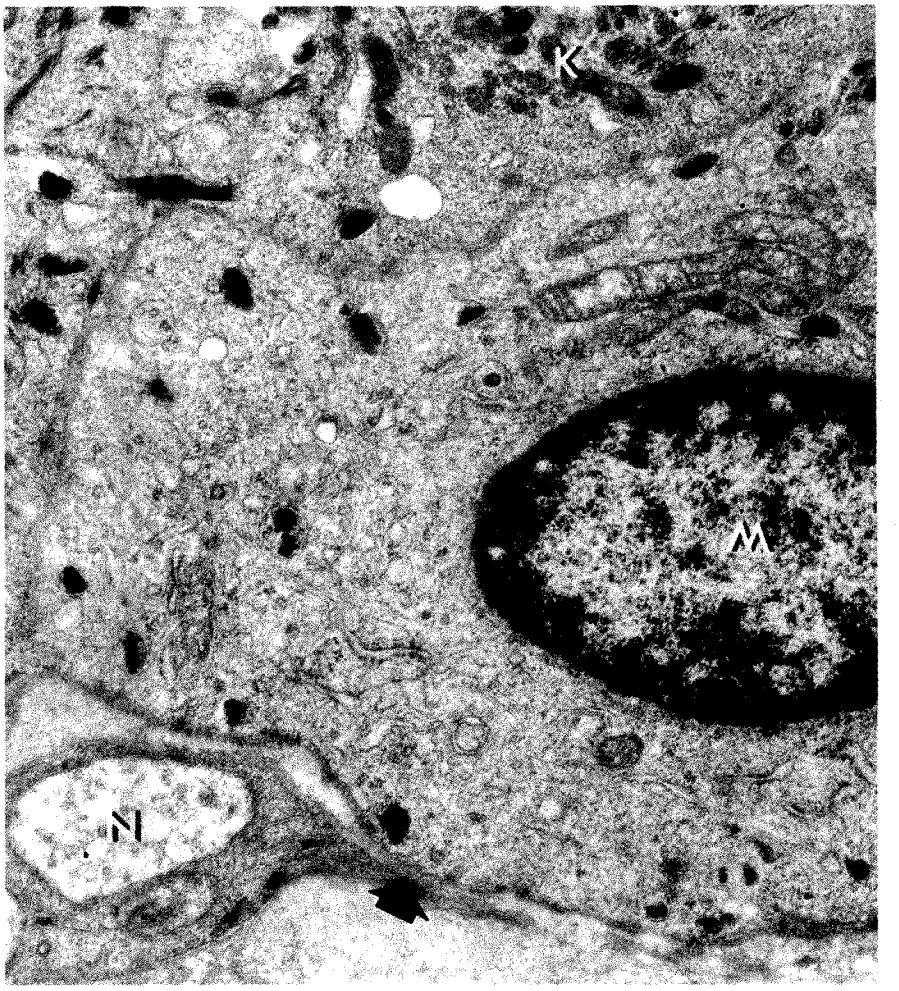

Fig 10.—Vogt-Koyanagi syndrome. Note direct association (dark arrow) between melanocyte (M) and nerve ending (N). Empty axon is due to fixation artifact. Keratinocyte indicated by K. Hypopigmented lesion (×17,000).

In the normal control skin taken from the incontinentia pigmenti achromians patients, nerve endings were also observed in close contact with the basal lamina of the epidermis. No melanocytes, however, showed either nuclear or cytoplasmic degeneration.

COMMENT

Degeneration of Melanocytes

In the present study, it was observed in all depigmenting conditions that melanocytes become coagulated, pyknotic, and presumably die. The same mechanisms of melanocyte degeneration were found in halo nevus.[7,8] The aggregation and autophagocytosis of melanosomes have been reported in degenerated melanocytes such as those in embryonic hair[16,17] and in other depigmenting

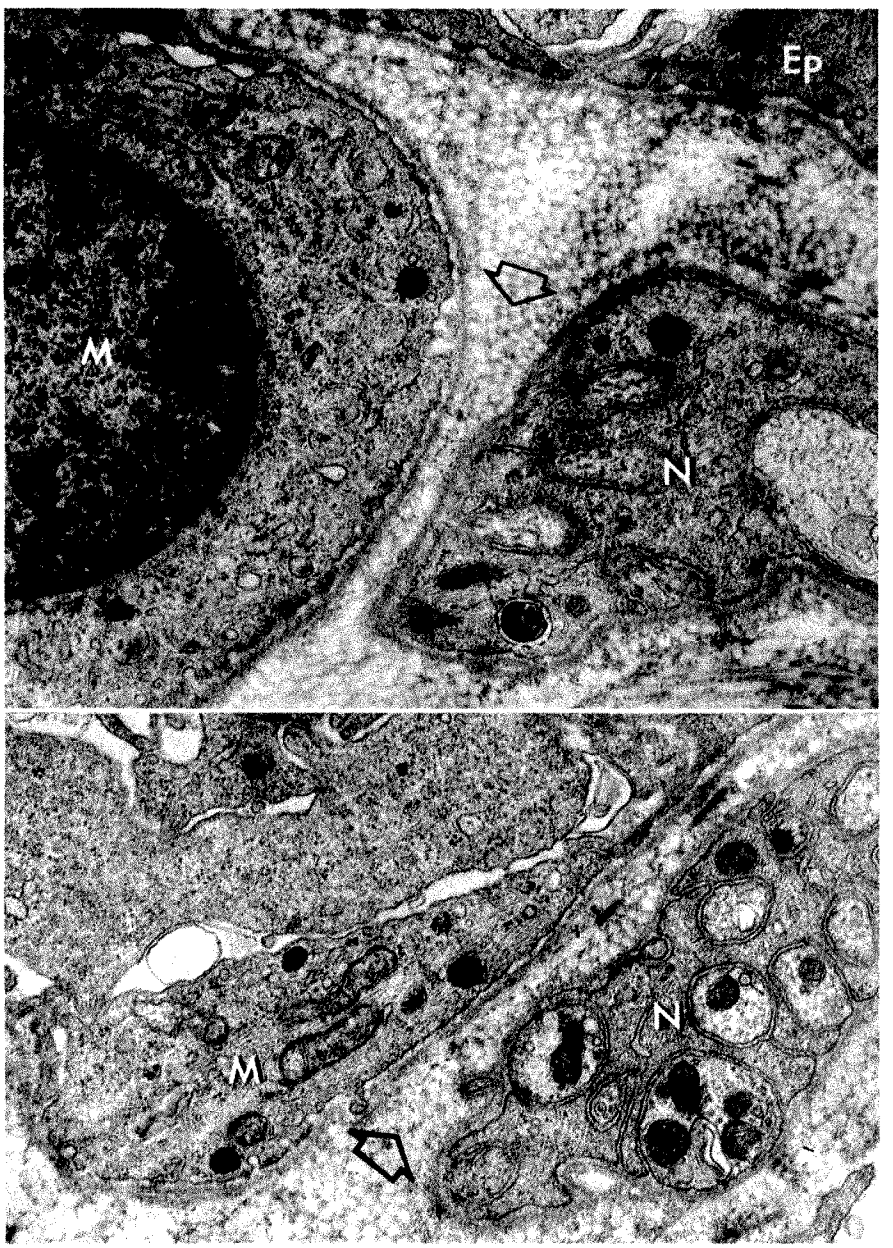

Fig 11.—Incontinentia pigmenti achromians (case 2). Top and bottom, Basal lamina of Schwann cells of nerve ending (N) in close association (hollow arrow) with basal lamina of melanocyte (M). Axons contain numerous mitochondria and neurotubules. Epidermis indicated by Ep. Hypopigmented lesion (×20,000).

conditions.[18,19] Since gradients of increasing severity of melanocyte degeneration were observed as the degree of depigmentation advanced from the normal to the hypopigmented areas in all diseases studied, it is surmised that a complete absence of melanocytes in the depigmented areas of these diseases also resulted from the same process of degeneration.

Applying the criterion that the epidermal melanocytes are connected to the basal lamina by hemidesmosomes,[13-15] many of the nonspecific basal dendritic cells[4,5] could be identified as nonpigment-producing melanocytes; the depigmentation in these diseases examined in the present study seems to be caused by both melanocyte degeneration and inactivation.

Nerve Connection to Melanocyte

The neural crest origin of the melanocyte is generally accepted and some investigators postulate that the epidermal melanocytes are under direct regulation of special nerves attached to them.[20] However, no ultrastructural proof has been presented. In the present study, a direct contact between melanocyte and nerve endings was shown in the hypopigmented skin lesions of three different depigmentary conditions. In a halo nevus case,[7] nerve endings were also demonstrated in the epidermis and the upper dermis. In view of the rarity of nerve ending-melanocyte association in the normal skin,[21-25] at least in the current literature, frequent association of nerve endings with melanocytes is, by itself, significant. Breathnach,[22] for example, stated that an axonal terminal with ensheathing Schwann cell process was observed to contact a basal epidermal cell "only once during five years of almost daily examination of the epidermal-dermal junction of interfollicular regions of human hairy skin."

On the other hand, Laties and Lerner,[26] while acknowledging the rare nerve-melanocyte association in the skin, reported that the sympathetectomized iris of brown-eyed rabbits became lighter. The tyrosinase activity of the melanocytes of such an iris decreased significantly (30% to 40%).

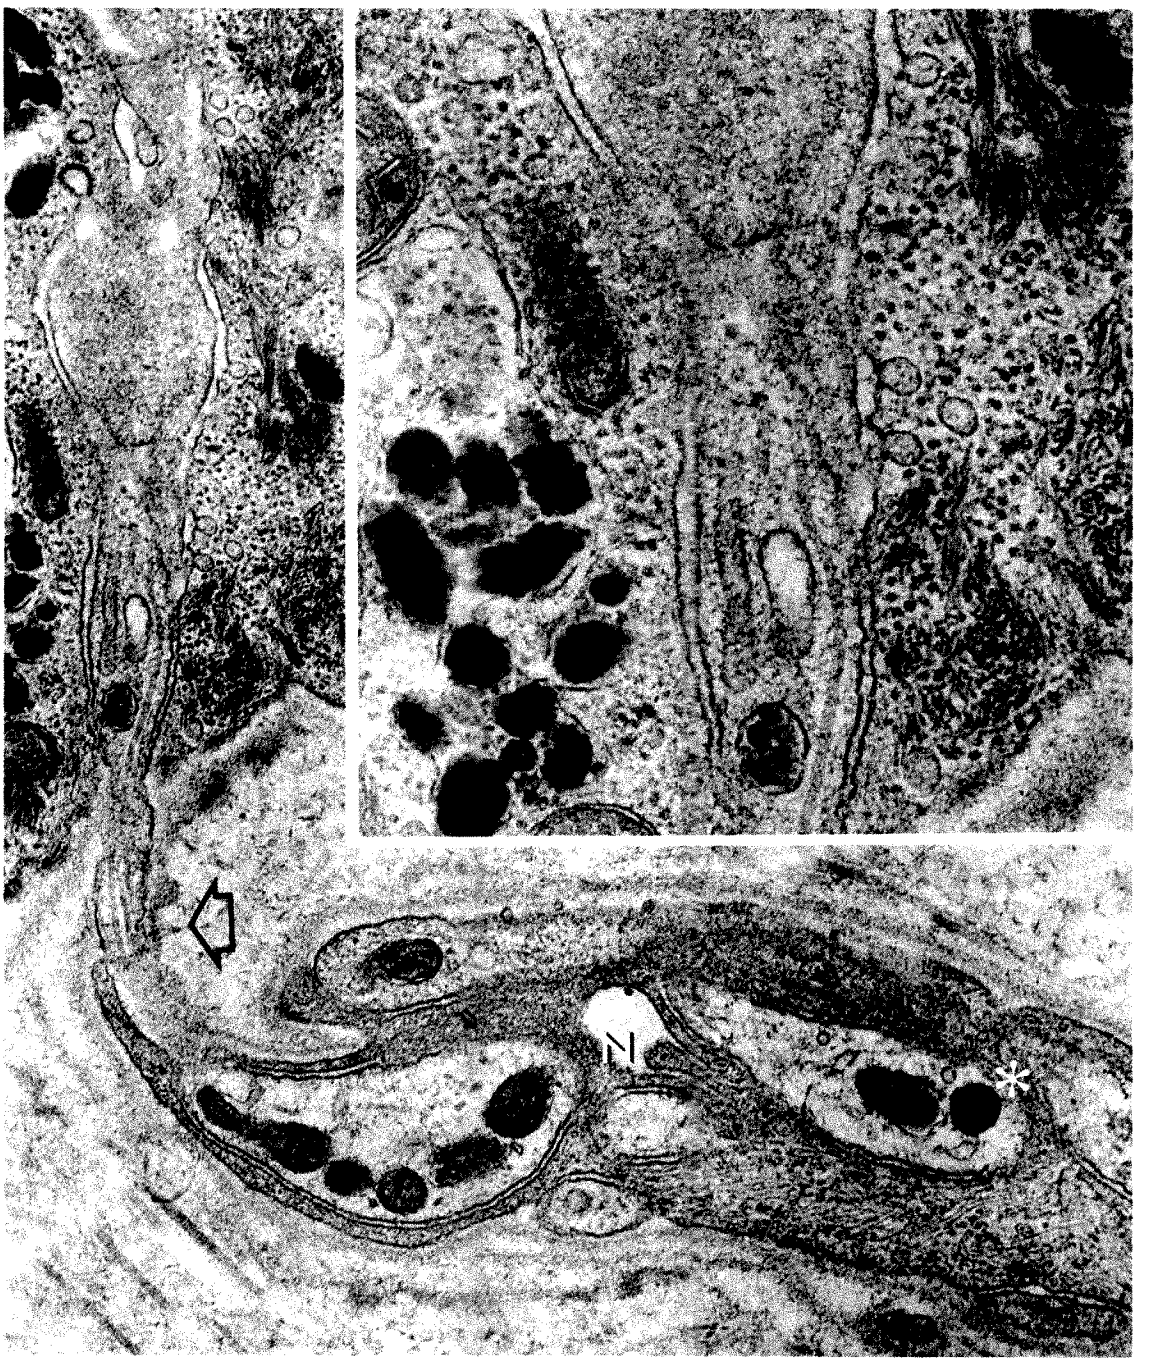

Fig 12.—Vitiligo (case 1). Low magnification of longitudinal section of nerve endings invading epidermis from dermis. Note direct continuity between Schwann cell basal lamina of nerve ending and basal lamina of epidermis (hollow arrow). Inset, Higher magnification of free nerve endings within epidermis. Hypopigmented lesion (×30,000; inset: ×58,000).

The assay of choroid melanocytes in the same eyes showed a similar decrease of tyrosinase activity. Although the iris contains stromal melanocytes that are directly innervated, it also has a posterior double lining of densely pigmented epithelial cells.

Since we have not engaged in an intensive search for nerve-melanocyte association in the normal skin, we are limited by the extent of the literature quoted.[21-25] We may have just detected in the lesion those nerve-melanocyte associations that may also be present in normal skin, simply because we examined the lesion very carefully.

With this reservation, one may speculate that an association of nerve endings with "normal" melanocytes in the lesion may signify the nerve-melanocyte contact initiates a degenerative process in the melanocytes; melanocytes undergo degeneration and the nerve invades the epidermis and replaces the melanocytes. Alternatively, those ultrastructurally "normal" melanocytes in the lesion may not be entirely normal in function; the nerve endings sense a subtle abnormality and approach them.

Dr Hashimoto is recipient of component projects 3499-01 and 3499-02 and the Medical Investigator award from the Veterans Administration.

Inflammatory Linear Verrucose Epidermal Nevus

A Pathologic Study

André Dupre, Bernadette Christol

• We saw three patients with inflammatory linear verrucose epidermal nevus (ILVEN). The purpose of this study is to better delineate the histopathologic features of this type of nevus. In fact, in all three cases very particular, specific histologic lesions have been noted that permit us to better distinguish this recently outlined entity. The histologic features were depressed, cup-like areas of hypergranulosis with overlying orthokeratotic hyperkeratosis, alternating (with sharp demarcation) with raised, level areas of agranulosis with overlying parakeratotic hyperkeratosis.

(*Arch Dermatol* 113:767-769, 1977)

Altman and Mehregan[1] and Kaidbey and Kurban[2] have reported differentiation of inflammatory verrucose epidermal nevus (ILVEN) from various other linear eruptions. Recently, we reported three cases in the French literature,[3,4] and others have also recognized cases of ILVEN.[5-7] Furthermore, we consider that some cases reported by others[8,9] under various diagnoses seemed to be ILVEN rather than the diseases that were suspected. This literature survey strongly suggests the existence of a unique dermatosis that has already been singled out in the texts of Unna[10] and Pinkus and Mehregan,[11] but which has been somewhat forgotten. The purpose of the present study is to better delineate the histologic features of ILVEN and to emphasize their specificity.

MATERIALS AND METHODS

Our study is based on the observation of three patients, the photographs of whom have already been published.[3,4] Case 1 was a 7-year-old girl whose lesions appeared at the age of 6 months. They were three parallel linear lesions localized on the right buttock. Case 2 was a 22-year-old man. The lesions, which are localized on the inner aspect of the left thigh, appeared at about the age of 6 months. They formed a rectangular plaque with a large longitudinal axis. Some linear verrucose lesions were scattered over the dorsum of the left hand. Case 3 was a 10-year-old boy. The nevus appeared at the age of 1 year and involved the whole left lower extremity with predominance of lesions in the following areas: testicle, groin, buttock, anterior aspect of the thigh, inner aspect of the knee, and dorsal surface of the foot (Fig 1).

In these three cases there was a strictly unilateral eruption, elective involvement of the proximal part of the lower extremities, juxtaposed lichenoid or verrucous papules, which were linear or reticulated in distribution, psoriasiform or eczematous in character, and accompanied by constant pruritus.

RESULTS

The histopathologic lesions of ILVEN are of two different types: nonspecific and specific. The nonspecific lesions include the following: (1) a diffuse, lymphohistiocytic inflammatory dermal infiltrate that was always present, showing a pericapillary predominance, and occasionally containing some granulocytes; and (2) hyperacanthosis with papillomatosis of a psoriasis type. The epidermal ridges are elongated, often narrow, closely set, and sometimes coalescing. The thickness of the malpighian layer remains normal, but the coalescence of the ridges leads to the formation of a plaque rising slightly above the cutaneous surface.

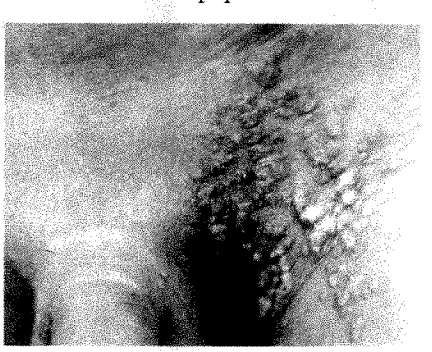

Fig 1.—Typical lesions on the thigh (case 3).

The epidermis very often consists of normal prickle cells. The occurrence of exoserosis and exocytosis in prickle cells has been emphasized by North American authors. These changes may lead to the formation of microabscesses, as occurs in psoriasis. In our cases, the exocytosis was mild or even absent.

The essential features of the specific lesions are as follows: There is an alternation of two types of keratinization processes, one with and the other without increase in granular cells (Fig 2 and 3). The areas of hypergranulosis are either very slightly or deeply depressed. When deeply depressed, they appear as cups, or as "pigeons' nests." There may be as many as four to eight layers of granular cells. Above each of these is an area of orthokeratotic hyperkeratosis, which is also depressed, cup-like, or funnel-like. The areas of agranulosis, on the contrary, are flattened, distinctly rising above the areas of hypergranulosis, forming an obtuse or table-like area. On top of these areas is thick parakeratosis.

The demarcation between the two areas is very sharp and very distinct at both levels: between the areas of agranulosis and hypergranulosis and between the areas of orthokeratotic and parakeratotic hyperkeratosis (Fig. 4).

Accessory Histopathologic Changes

Three histologic types of changes

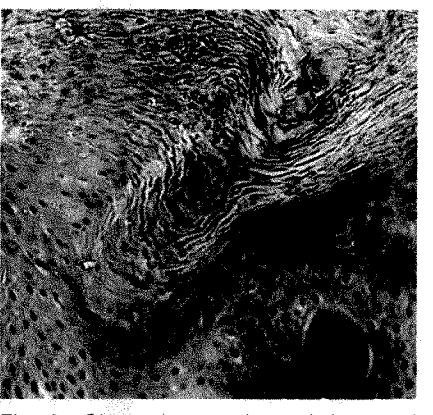

Fig 8.—Sharp interruption of layer of hypergranulosis resulting in column of parakeratotic cells.

are encountered in the areas of parakeratotic hyperkeratosis: (1) lamellar parakeratosis, in which there are numerous parakeratotic lamellae, arranged in dense and closely set strata, which sometimes tend to separate from each other but remain anastomosed together; (2) spongy parakeratosis of reticulated type with formation of globular horny masses varying in volume; and (3) parakeratosis with folded lamellae; in some areas, these lamellae seem to invaginate, to sink, wedge-shaped, into the epidermis. They appear, therefore, as "geological folds," tufts, or whorls (Fig 5 and 6). The areas of agranulosis may be very broad or, on the contrary, so narrow that the overlying area of parakeratosis may resemble a pile of plates (Fig 7 and 8), quite similar to the cornified lamella of Mibelli porokeratosis.

The two types of keratogenesis may alternate at short spatial intervals (Fig 2-4 and 7); in that case, the microscopic appearance is very distinctive and the diagnosis can be made readily. Sometimes the intervals are broad. That is, in one section there may be only a wide area of agranulosis delimited in the periphery by areas of hypergranulosis. These areas of hypergranulosis are then of great diagnostic value. However, this is evident in some complex pictures in which, for example, a layer of hypergranulosis, a layer of parakeratotic hyperkeratosis, and one of orthokeratotic hyperkeratosis are found one above the other. Such pictures indicate that the type of keratinization of a determinate area can change. An area that appears in a state of hypergranulosis later may become an area of agranulosis, and vice versa.

COMMENT

The consistent findings in three patients permit determination of the histologic criteria of ILVEN. Alterations in two types of keratinization have already been mentioned by several authors[1,2,8,9], but have not been explored enough. Our histologic criteria may not be found in all biopsy specimens; in some cases, and in particular when only a small biopsy specimen is available for study, the alternation perhaps will be less obvious than in our descriptions.

These findings indicate that ILVEN is a clinical and a histologic entity in which keratinization undergoes abrupt and complete changes to produce either orthokeratotic or parakeratotic hyperkeratosis. It seems as if the mixed keratinization has a mosaic structure consisting of the disorderly juxtaposition of variously sized areas of the opposite types. We believe that this phenomenon is unique in skin histopathology. An abrupt transition between or sharp margination of orthokeratotic from parakeratotic horn in alternating arrangement indeed is seen in such disparate pathologic processes as parakeratosis (Mibelli, disseminated superficial actinic, punctuate, and linear) and solar keratosis. However, in our opinion, the alternation of table-like parakeratotic areas and depressed orthokeratotic areas occurring at regular spatial intervals seems quite specific.

We cannot explain the sudden changes in the keratinization process. There is no alteration of the underlying acanthotic epidermis, and this seems to suggest that the pickle cell layer is apparently unaffected; exoserosis and exocytosis are often mild and sometimes absent. Moreover, the dermal infiltrate is definitely not responsible for the dyskeratogenesis. The infiltrate is very mild, nonspecific, and homogeneously distributed; it is found in the whole dermis, under the areas of agranulosis as well as under the areas of hypergranulosis. It is thus accessory, being the result and not the cause of the dyskeratogenesis. Therefore, ILVEN appears to be a disorder with very specific keratinization. Diseases with such a distinctive histologic substrate are rare in dermatology.

Phototoxicity Occurring During the Manufacture of Ultraviolet-Cured Ink

Edward A. Emmett, MB, BS; Barbara R. Taphorn; John R. Kominsky, MS

• **Four workers employed in the manufacture of ultraviolet-cured inks complained of photosensitivity characterized by an intense burning sensation during sun exposure. Three of these workers developed dermatitis on exposed areas following sun exposure. Six compounds used as photoinitiators in the ink formulations were found to absorb solar ultraviolet radiation. Two preparations of mixed isomers (ortho and para) of amyl dimethylaminobenzoate were found to be phototoxic to Ehrlich ascites cells in vitro and to produce diphasic phototoxic reactions in vivo after topical application on symptomatic workers, asymptomatic workers, or previously unexposed subjects. These responses could be prevented in two subjects by the application of a 10% sulizobenzone sunscreen prior to sun exposure. Two other photoinitiators, Michler's ketone and thioxanthone were phototoxic in vitro but not after topical application in vivo.**

(*Arch Dermatol* 113:770-775, 1977)

Several men employed in the formulation of ultraviolet (UV)-cured inks complained of photosensitivity. In this article, we describe the investigation of these complaints and the finding that two preparations of mixed isomers of amyl dimethylaminobenzoate designated as absorber A and absorber B in the form in which they were used in this process were able to induce phototoxic responses both in vitro and after applications to human skin. Two other materials, thioxanthone and Michler's ketone were phototoxic in vitro, but a phototoxic response could not be demonstrated from topical application in vivo.

ULTRAVIOLET-CURED INKS

Ultraviolet cured inks are of relatively recent development but their use is becoming widespread. The ink composition varies but usually consists of one or more conventional pigments dispersed in a polymeric vehicle. The vehicle usually contains the following: (1) various polyfunctional acrylic monomers such as trimethylol propane triacrylate or pentaerythritol triacrylate, alone or in combination with monofunctional acrylic monomers; (2) an UV reactive unsaturated polymer such as acrylated urethane polyester oligomer, acrylated epoxy resin oligomer, and a variety of other types of acrylic base polymers; (3) one or more photoinitiators such as benzophenone, or isomers of amyl dimethylaminobenzoate; (4) diluents such as primary and aliphatic alcohols or phthalates; (5) hydrogen transfer agents such as triethanolamine; and (6) a variety of miscellaneous agents, including stablizers, surfactants, fillers, flattening agents, and polymerization inhibitors.

The first step in the curing process is the absorption of UV radiation by the photoinitiator (such as benzophenone). The absorption of UV results in the generation of free radicals or other photoexcited states, which in turn cause polymerization of the vehicle in which the pigments are incorporated and thus cure of the ink film. Medium pressure mercury arc lamps are generally used for the cure.

Table 1.—Clinical Features in Four Employees Complaining of Photosensitivity

Characteristic	Employees 1	2	3	4
Symptoms	Burning on exposed areas within 5-10 minutes' sun exposure; exposure and swelling (lasting 2-3 days) after sun exposure	Burning on exposed areas within 5-10 minutes' sun exposure; erythema and swelling occur within a few hours of exposure	Burning on exposed areas within a few minutes of sun exposure, including sunlight through car window	Burning on exposed areas within a few minutes of sun exposure
Observed morphology	Erythema with sharp margin on V of neck and dorsal aspects of hands; lichenification of forearm	Erythema with fairly sharp margin on dorsal surface of both forearms	Erythema with sharp margins on forearms, outer surface of ears, and V of neck, sparing submental area	None
History of preexisting dermatitis	History of recent vesicular eruption on arms; severe exacerbation following sun exposure	No preexisting dermatitis	Recent intermittent itching, erythema, swelling, and scaling of forearm	Dermatophyte infection of feet
Results of closed patch testing with ink resin components*	Pentaerythritol triacrylate 0.2% in petrolatum: + +* Trimethylpropane triacrylate 1% in petrolatum: + + + Hexanediol diacrylate 1% in petrolatum: + + epoxy acrylate 1% in petrolatum: + +	No positive reactions	Pentaerythritol triacrylate 0.2% in petrolatum: + + Trimethylpropane triacrylate 1% in petrolatum: + + Hexanediol diacrylate 1% in petrolatum: + + Epoxy acrylate, 1% in petrolatum: +	No positive reactions

*Grading of reactions performed, using the scale recommended by the International Contact Dermatitis Group (1): negative reaction, —; doubtful reaction, ?+; weak (nonvesicular) reaction, +; strong (edematous or vesicular) reaction, + +; and extreme reaction, + + +.

CLINICAL FEATURES

Four white men, aged from 26 to 52, employed weighing, mixing, or milling UV-cured inks, complained of sensitivity to sunlight. The clinical characteristics in these subjects are given in Table 1. Subjective complaints included burning (smarting) on exposed areas occurring within a few minutes of sun exposure, persisting until the exposure ceased and erythema and swelling occurring within minutes to hours of sun exposure and lasting for up to several days. In two of the men, there was evidence of eczematous dermatitis, in both cases apparently due to allergic contact sensitization to certain acrylates used in the UV-cured ink formulation. The results of patch testing with these materials are shown in Table 1. In both men, the occurrence of marked smarting on sun exposure suggested additional photosensitivity, in one subject additional severe exacerbations of his eczematous lesions were described following sun exposure while gardening.

The unprotected skin and clothes of these men were frequently occupationally contaminated with components of the UV-ink. In no case was there a history of taking any known photosensitizing drug within the last year, a family history of photosensitivity, or clinical evidence of any disease known to be associated with photosensitivity. In each case, the burning sensation on sun exposure had not been present prior to exposure to UV-cured ink components and appeared temporally related to the manufacture of ultraviolet-cured ink.

INVESTIGATION OF PHOTOSENSITIVITY METHODS

Absorption Spectra.—In order to determine which of the materials used in the UV-cured ink formulation might cause photosensitization, the UV absorption spectra of all ingredients were determined in ethanol using a double beam spectrophotometer (Coleman 124).

In Vitro Phototoxicity.—Each of the UV-cured ink ingredients that absorbed UV radiation above 290 nm was evaluated for phototoxicity in an Ehrlich ascites cell system.

Ehrlich ascites cells were harvested from a mouse eight to ten days after implantation. After an initial staining with trypan blue and counting to ensure that the cells were viable, the cells were washed twice in lactated Ringer's solution before being put in suspension at a concentration of 2×10^6 cells/ml. Four sets (A, B, C, and D), each of two cell suspensions, were then studied. Sets A and B were incubated with the test material in the dark for two hours at room temperature, sets C and D were similarly incubated with the Ringer solution vehicle. After incubation, the cells were washed twice before being resuspended in lactated Ringer's solution in small Petri dishes. Sets A and C were then irradiated at a room temperature of 24 C, while sets B and D remained in the dark. The percentage of dead cells in each sample was determined 24 hours later by staining with the nonvital dye trypan blue. Cells were stained with this dye in the dark for at least two minutes before readings were made. Duplicate readings of at least 200 cells each were performed on each cell suspension. The mean and variance was calculated for the four percentage counts obtained on each set of results and the results for the different sets compared by the analysis of variance of a two by two factorial. In this way, it could be determined whether an interaction between the irradiation and the incubated chemical had occurred. Significance was determined using a two tailed t-test. The phototoxicity assay was recorded as positive when a statistically significant ($P < .05$) interaction between irradiation and the incubated chemical was determined in the above manner. The cells were irradiated either for ten minutes at a distance of 30 cm from a bank of four sunlamps (predominantly 293 to 325 nm radiation) or for one hour at a distance of 30 cm from a bank of four BLB40 black lights (predominently 330 to 380 nm radiation). The radiant exposure from the sunlamps measured with an IL700 spectroradiometer detector and narrow-band filter with a maximum spectral response at 297 nm and half power points at 291 and 303 nm was 9.4×10^{-6} joules/sq m. The

radiant exposure from the black lights measured with a IL700 spectroradiometer and detector with a wide-band filter with maximum response at 365 nm and half power points 330 and 400 nm was 4.1×10^{-4} joules/sq m. This exposure from the bank of sunlamps was sufficient to produce a slight decrease in the viability of control cells, whereas no alteration in the control cells was seen following this exposure from the blacklights. Where the compounds were not readily soluble in water, 5% ethanol in lactated Ringer's solution was used in place of lactated Ringer's solution for the incubation step. For each test, preliminary incubations at varying concentrations of the test material with the Ehrlich ascites cells were made in order to determine nontoxic concentrations for incubation.

Photopatch Testing.—Photopatch testing was performed on three employees (subjects 1 through 3), who complained of photosensitivity and four employees free of photosensitivity using the following UV-cured ink components: benzophenone, 5% in petrolatum; diethoxyacetophenone, 5% in petrolatum; thioxanthone, 5% in petrolatum; Michler's ketone, as is; absorber A, 5% in petrolatum; absorber B, 5% in petrolatum; absorber A, as is; and absorber B, as is.

Ink components used for photopatch testing were applied evenly to the central gauze portion of adhesive plastic strips 3.8 sq cm in size before application to the skin. Two duplicate sets of patches were applied to the back and were covered, secured, and occluded with several layers of hypoallergenic surgical tape. One set of patches was removed 24 hours after application and the area gently cleansed with 70% ethanol in water. These sites were then exposed to sunlight. Four employees working a day shift were exposed to 25 minutes of clear noon, July, Cincinnati (39 degrees north) sunlight and three employees to 35 minutes of sunlight from 3:50 PM that same day. Reactions were observed during the irradiation. The second set of patches that functioned as a dark control for the development of allergic contact or irritant reactions was removed 48 hours after application and the site gently cleansed with 70% alcohol. Reactions at both sites were read and graded one hour later.

In two subjects complaining of photosensitivity, the minimal erythema dose (MED) was determined as previously described,[2] an area 5 × 10 cm was irradiated with four times the MED and photopatch testing performed with a routine tray of diphenhydramine hydrochloride (Benadryl) cream; bergamot oil, 10% in petrolatum; bithionol 1% in petrolatum; 4'5 dibromosalicylanilide, 1% in petrolatum; eosin, as is; hexachlorophene, 0.5% in petrolatum; promethazine hydrochloride (Phenergan Cream), as is; tripelennamine (Pyribenzamine), 1% in petrolatum; tribromosalicylanilide, 1% in petrolatum; trichlorocarbanalide, 0.5% in petrolatum; triflurocarbanalide, 0.5% in petrolatum; and ragweed oleoresin.

In Vivo Phototoxicity and Photoprotection.—Two patches each of purified amyl *p*-dimethylaminobenzoate—absorber A and absorber B were applied as described above to the backs of four white subjects, aged 25 to 35, who had no previous industrial exposure to amyl *p*-dimethylaminobenzoates. Purified amyl *p*-dimethylaminobenzoate was also examined as were the two absorbers represent mixed isomers (para and ortho) dimethylaminobenzoate. After 24 hours one set of patches was removed and the area lightly cleansed with 70% ethanol in water while the second set was covered with an additional layer of black plastic tape. Twenty minutes after removal of the first set of patches, subjects were exposed to clear, noonday, Cincinnati (39 degree north) sunlight on Aug 5, 1975, for 30 minutes. Immediately afterwards, the second, previously occluded set of patches was removed and the area similarly cleansed with 70% ethanol in water. On three subjects, a third and fourth set of patches were applied that were also removed and the areas cleansed 20 minutes before sun exposure. The third set was immediately evenly covered with 2.5 μl/sq cm of a sunscreen containing 5%-*p*-aminobenzoic acid in alcohol (Presun) and the fourth evenly covered with 2.5 μl/sq cm of a sunscreen containing 10% sulisobenzone (Uval) 15 minutes prior to sun exposure. The reactions were observed during sun exposure, hourly for 5 hours and again 48 and 72 hours after patch application. No subjects had further sun exposure over this observation period.

RESULTS

Six photoinitiators used in UV-cured inks were found to absorb UV radiation above 250 nm namely benzophenone, thioxanthone, 2,2-diethoxyacetophenone, 4,4'-bis (dimethylamino) benzophenone (Michler's ketone), and two different commercial preparations of industrial grade mixed isomers of amyl dimethylaminobenzoate designated as absorber A and absorber B. The absorption peaks of these substances in alcohol are shown in Table 2. Absorber A had an absorption peak at 310 nm (ϵ -15,000) with one half the peak absorption at 288 and 326 nm, absorber B an absorption peak at 310 nm (ϵ = 20,000) with one half the peak absorption at 289 and 325 nm. Pharmaceutical grade amyl *p*-dimethylaminobenzoic acid had an absorption peak at 306 nm (ϵ = 30,000) with one half the peak absorption at 287 and 322 nm. Amyl ortho dimethylaminobenzoic acid has an absorption peak at 344 nm.

The results obtained from the in vitro phototoxicity assay of these substances using Ehrlich ascites cells are shown in Table 3. It will be seen that benzophenone and diethoxyacetophenone were not demonstrably phototoxic whereas Michler's ketone, thioxanthone, and the two absorbers containing mixed isomers of amyl dimethylaminobenzoate were phototoxic in this system. Both light sources, sunlamps and black lights, produce comparable results. Purified amyl *p*-dimethylaminobenzoate and *p*-aminobenzoate were also examined for phototoxicity in the same manner. As seen from the table, the amyl *p*-dimethylaminobenzoate was phototoxic whereas *p*-aminobenzoic acid was not. No phototoxicity was seen whether *p*-aminobenzoic acid was examined dissolved either in lactated Ringer's solution or 5% alcohol in lactated Ringer's solution.

The results of phototesting observed on three employees complaining of photosensitivity (subjects 1, 2, and 3 of Table 1) and four other employees not complaining of photo-

sensitivity are shown in Table 4. The majority of subjects complained of a sharp stinging or burning sensation within a few minutes of sun exposure localized to the exposed areas where absorber A as is, and absorber B, as is, had been applied. Four subjects developed sharply marginated erythema and two faint or questionable erythema responses on the absorber A site during sun exposure and three subjects sharply marginated erythema and two faint questionable erythema at the absorber B site during sun exposure. Twenty-four hours after sun exposure, six of the seven men (including subject 7, a deeply pigmented black) had a reaction consisting of uniform erythema and edema on the area exposed to undiluted absorber A and sunlight; two of the seven men also had reactions to undiluted absorber B under the same conditions. No reactions were seen to absorbers A or B on sites occluded from sunlight. No reactions were seen with the other UV ink components phototested either on exposed or occluded sites, apart from a single weak reaction to Michler's ketone on a patch test site occluded from sunlight that was interpreted as an irritant reaction. No reactions were seen on sun-exposed or control sites tested with either absorber A or absorber B diluted to 5% in petrolatum. Photosensitive subjects 2 and 3 had further testing. Both had a normal minimal erythema dose; negative photopatch testing with a routine tray, no demonstrable circulating antinuclear antibody, and no abnormal reaction at 24, 48, or 168 hours to irradiation with

four times the minimal erythema dose of UVB.

In order to examine the characteristics of the phototoxic responses to absorber A and absorber B more closely, further observations were made on the phototoxic responses in four individuals without previous known industrial exposure to these materials. Observations were also made on the photoprotective effect of sunscreens representative of two different classes of sunscreens in three of these individuals. Three of the four subjects noted a sharply localized intense burning sensation that commenced a few minutes after the areas patch tested with absorbers A and B were exposed to sunlight. No burning occurred on the covered areas. The burning sensation was accompanied by erythema, and in one case, prominent edema. One subject also developed erythema and a burning sensation at the site of application of the purified amyl *p*-dimethylaminobenzoate. In each case, the burning stopped within a few minutes of the cessation of sun exposure.

The reaction was observed to be diphasic, the erythema and swelling began to fade shortly after sun exposure ceased and had disappeared in two subjects within one hour and in the third, more severely affected subject, two hours after sun exposure ceased. Four to five hours after the sun exposure, erythema recurred and remained for two to five days. Mild discomfort and irritation accompanied the reappearance in each case, but the intense burning noted during sun exposure was not evident. The reactions noted in each subject immediately following and 24 hours after sun exposure are shown in Table 5.

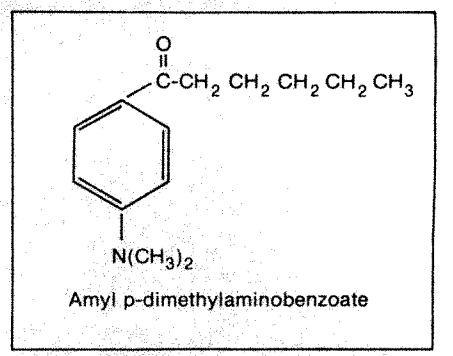
Two of the three subjects to whom sunscreens were applied developed a phototoxic response so that the degree of photoprotection could be estimated. As seen from Table 5, the prior application of a 5% *p*-aminobenzoic acid sunscreen provided partial protection against the reaction whereas the application of a 10% sulisobenzone sunscreen was able to completely suppress the development of the phototoxic response under the conditions of exposure.

COMMENT

The two industrial preparations of mixed isomers of amyl dimethylaminobenzoate designated as absorber A and absorber B were demonstrated to be phototoxic with either UVA (280 to 315 nm) or UVB (315 to 400 nm) to Ehrlich ascites cells in vitro and with sunlight to human skin in vivo. The phototoxic reaction could be reproduced even in deeply pigmented black skin. The phototoxic nature of the in vivo responses was indicated by the relative immediacy of the response to sunlight, the intense burning sensation on exposure to sunlight, the ability to reproduce the reaction in other employees not complaining clinically of photosensitivity, as well as in previously unexposed persons, and the failure of reactions to occur when these substances were diluted. The chemical structure of amyl *p*-dimethylaminobenzoate is shown in the Figure. Although Michler's ketone was noted to be phototoxic in vitro, a phototoxic response to this substance could not be reproduced by topical application to human skin and subsequent exposure to sunlight. Thioxanthone also gave a phototoxic response in vitro, but not at 5% concentration in vivo and was not studied further as it had rarely been used in the industrial process.

Two of the four employees complaining of photosensitivity also had allergic contact sensitization to acrylic monomers and epoxy acrylate oligomers to which they had been exposed. However, sun exposure of skin involved in allergic contact dermatitis does not usually provoke the very intense burning sensation and the exacerbations of dermatitis that these subjects described.[3,4] Their photosensitivity seems better explained as clinical phototoxic reactions to the undiluted absorbers A and B that they handled during their work.

It has been previously suggested[5] that the allergenicity of benzyl salicylate, a weak contact sensitizer, may have been enhanced by the phototoxic effect of simultaneously applied topical methoxsalen. The same effect may have enhanced the allergenicity of the acrylate monomers and epoxy acrylate oligomers in this instance. One



Chemical structure of amyl dimethylaminobenzoate.

could also speculate that the simultaneous allergic contact dermatitis in several of these employees with attendant damage to the epidermal barrier might have increased the penetration of the phototoxic materials and thus rendered the phototoxic response more easily elicitable.

The phototoxic reactions observed on human skin after experimental application of the two industrial absorbers were noted to be diphasic. The burning sensation (smarting reaction) described during sun exposure and the ensuing dermatitis observed by employees appear to parallel the two phases. The initial intense smarting reaction on sun exposure has been noted in other phototoxic reactions, such as those occurring in pitch workers[6] and is common to all crude coal tars. In addition, demeclocycline hydrochloride (Declomycin) phototoxicity is associated with paraesthesiae during sun exposure, and burning and itching during sun exposure are commonly observed in patients with erythrocytic protoporphyria. In the case of the mixed isomers of amyl dimethylaminobenzoate, the initial burning was also accompanied by erythema and sometimes transient wheal formation confined to the site of the reaction. This reaction disappeared completely before the recurrence of erythema and discomfort some hours later.

The phototoxic reactions observed with the two industrial preparations of undiluted mixed isomers of amyl dimethylaminobenzoate was somewhat surprising as purified amyl *p*-dimethylaminobenzoate is demonstrably effective at a 5% concentra-

tion as a sunscreen.[7] No phototoxicity was observed in these employees when a 5% concentration of amyl *p*-dimethylaminobenzoic acid was applied. A difference between protective and toxic responses depending on the circumstances of use would seem to illustrate the important toxicologic principle that the hazard from any material is highly dependent on the circumstances of its use. The phototoxic reaction on human skin with pure amyl *p*-dimethylaminobenzoate was less marked than with the mixed isomer preparations suggesting that other isomers may be the most important phototoxic agents. However, pure amyl *p*-dimethylaminobenzoate could be observed in vitro to be phototoxic, whereas neither benzophenone nor *p*-aminobenzoic acid were observed to be phototoxic in vitro.

The phototoxic effect observed on the skin of volunteers could be blocked by the prior topical application of a 10% sulisobenzone (2-hydroxy-4-benzophenone-5 sulphonic acid) preparation but only partially blocked by a similar application of 5% *p*-aminobenzoic acid in alcohol. This suggests that sulizobenzone preparations which are effective screens in the UVA as well as the UVB range[1] may prove useful sunscreening agents for use in accidental skin contamination by the amyl dimethylaminobenzoate esters. The relative ineffectiveness of *p*-aminobenzoic acid (absorption maximum in water 266 nm, absorption extending to 310 nm) presumably depends on its ineffectiveness against the wavelengths of 310 and greater. Although it has been held that only physical sunscreens such as zinc oxide, titanium dioxide, or red veterinary petrolatum are effective against industrial phototoxic agents,[8] there seems to be no good reason why a sunscreen eliminating the requisite wavelengths cannot satisfactorily block phototoxic responses as has been recently demonstrated in the case of vinblastine.[9]

Vegetables Responsible

Syamalendra M. Sinha, MD; Jagjit S. Pasricha, MD, PhD; Ramesh C. Sharma, MSc, PhD; Kahn C. Kandhari, FRCP

• **Fifty-three patients having contact dermatitis on the fingertips showed positive patch tests with several vegetables, the commonest being garlic, onion, tomato, and carrot in that order of frequency. Of several preparations, made from garlic, onion, tomato, and carrot, the juices used as such gave the maximum number of positive patch test reactions. Lyophilization of the juices led to false-negative patch tests in some cases. Patch tests in the controls were positive in some cases but these were probably cases of latent hypersensitivity, because some of them, like the patients, showed positive reactions even with the diluted juices. The antigens in garlic and onion were extractable in water, ether, acetone, or alcohol and were also present in the essential oils of these vegetables. Infrared spectra of the essential oils of garlic and onion were similar and showed straight chain acids, esters, and methylene groups. Clinically, there was no suggestion of cross-sensitivity between onion and garlic.**

(*Arch Dermatol* 113:776-779, 1977)

Many housewives in north India have hyperkeratosis, scaling and fissures on the tips of the thumb, the index, and the middle fingers of one or both hands associated with severe itching. Most of these patients report aggravations of the lesions following contact with raw vegetables, and in a pilot study, all the patients showed positive patch tests with the juices of one or more vegetables. The literature on this subject[1-9] tends to create the impression that contact dermatitis due to vegetables is uncommon and occurs mainly among workers in the canning industry. We are reporting our findings on the frequency with which various vegetables produce contact dermatitis, results of patch tests with various types of preparations from some vegetables, and some data on the identification of the chemicals responsible for hypersensitivity.

Accepted for publication Nov 8, 1976.

CLINICAL DATA

In two years, 53 patients (49 women and four men) were seen with contact dermatitis due to vegetables. All the women were engaged in household work; while two men were employed as cooks and the remaining two men used to cook as a hobby. All patients showed hyperkeratosis, scaling, fissuring, and erythema on the palmar aspects of the tips of the thumb, the index, and the middle fingers. Three patients had involvement of the dorsal aspects of the fingers also. In 48 patients, both the hands were involved; in three, the lesions were present only on the right hand; and in the remaining two, only the left hand was involved.

PATCH TESTS

Patch tests were performed in every case with the freshly extracted juices of all the vegetables used by the patient, using 0.05 ml of the juice per patch. The results were read on the third day, and the patch test was considered to be positive only if it produced at least a 2+ reaction. In general, recommendations of Fisher[10] were followed.

Table 1 shows the number of patients who showed positive reactions to various vegetables. Garlic (*Allium sativum*), onion (*Allium cepa*), tomato (*Lycopersicon esculentum*), and carrot (*Daucus carota*) were responsible for the maximum number of positive reactions in that order of frequency. Less frequently, other vegetables also produced positive patch tests. By preventing further exposures to the respective vegetables, none of the patients had a recurrence. Routine patch tests with soaps, common household detergents, and nickel sulfate were negative in all cases.

Patch Tests With the Prepared Antigens of Garlic, Onion, Tomato, and Carrot

Standard varieties of onion (Pusa-Red),

or Contact Dermatitis of the Hands

tomato (Pusa-Ruby), and carrot (Pusa-Keshar) were obtained from the Indian Agricultural Research Institute, New Delhi, while garlic was purchased from the market. Each of these vegetables was cleaned, peeled, and crushed in a mechanical extractor to obtain the juice. The remaining pulp was mixed with one half its weight of water, kept at room temperature overnight, and filtered to obtain the extract. A part of the juice was evaporated to dryness in a lyophilizer, and the residue was redissolved in distilled water to make the original volume. This will henceforth be called the solution. To assess the degree of hypersensitivity of different patients, aliquots of each of the juice, the extract, and the solution were diluted with distilled water to make 50%, 20%, and 10% concentrations. Eleven patients each, known to be allergic to garlic and onion respectively, five patients allergic to tomato, and two patients allergic to carrot were tested with various preparations of the respective vegetables and their various dilutions. In addition, every patient was also tested with the freshly extracted juice of the respective vegetable to assess the possibility of nonspecific irritant reactions with fresh juices of vegetables.

The results are shown in Table 2. All the allergic patients showed positive patch tests with the freshly extracted juice of the corresponding vegetable; the prepared juices gave comparable results, except that two patients each tested with onion and tomato gave negative patch tests. The solution and the extract of various vegetables showed negative patch tests in several patients. Dilution of the vegetable juices to 50% concentration resulted in negative reactions in some patients, though some patients showed positive patch tests even with 10% concentration of the juice.

Controls

Four groups of 20 patients each, having contact dermatitis due to some other substance, were taken as controls and tested with the fresh as well as the prepared juices of garlic, onion, tomato, and carrot, respectively. They were also

Table 1.—Incidence of Positive Patch Tests With Various Vegetables

Vegetable	Botanical Name	No. of Patients Having Positive Patch Test
Garlic	*Allium sativum*	44
Onion	*Allium cepa*	30
Tomato	*Lycopersicon esculentum*	10
Carrot	*Daucus carota*	9
Lady's finger	*Hibiscus esculentus*	6
Ginger	*Zinziber officinale*	6
Brinjal	*Solanium malongena*	6
Radish	*Raphanus sativus*	5
Cauliflower	*Brassica oleracea*	5
Potato	*Solanum tuberosum*	4

Smooth luffa	*Luffa acutangula*	1
Spinach	*Spinacia oleracea*	1
Round gourd	*Citrullus vulgaris*	1

tested with various dilutions of the prepared juices.

With the fresh juices, seven controls were positive with garlic, three with onion, four with tomato, and one with carrot, while with the prepared juices, five controls were positive with garlic, and two each with onion and tomato. Some of these controls were positive even with the diluted vegetable juices.

Out of another group of 20 controls tested with fresh garlic juice only used as such, five showed positive patch tests.

Patch Tests With Different Varieties of Onion

The following five different varieties of onion were obtained: (1) N-53, red; (2) N-24-1, red; (3) N-257-9-1, white; (4) N-5-7-1, white; and (5) N-123-7-1, white. Onion juices were obtained from each of these varieties by a juice extractor and used as such for patch tests on five patients allergic to onion and one control subject.

Positive patch test reactions of almost equal intensity were obtained with all the five varieties of juices in all the five patients who were allergic to onion, but the tests in the control subject were negative.

Extraction of the Antigens From Onion and Garlic

One hundred grams of onion of the Pusa-Red variety were peeled, chopped, and kept immersed in 150 ml of petroleum ether in a percolator at room temperature for 24 hours. At the end of this period, the ether was decanted, and the onions were mixed with 150 ml more of petroleum ether. Three washings of petroleum ether collected on three consecutive days were pooled to constitute the ether soluble fraction. The residue of the onions was then extracted with three successive changes of 150 ml each of acetone and then with absolute alcohol, and finally with water to give acetone soluble, alcohol soluble, and water soluble fractions, respectively. Each of these fractions was evaporated to dryness and then redissolved in 1 ml of water.

One hundred grams of garlic purchased from the market were also processed in the same manner to obtain ether soluble, acetone soluble, alcohol soluble, and water soluble fractions of garlic.

Patch tests were performed with all these fractions of onion on four patients known to be allergic to onion and five control subjects, while fractions obtained from garlic were tested on seven patients allergic to garlic and six control subjects.

All the four patients allergic to onion showed positive patch tests with the ether soluble, acetone soluble, and alcohol soluble fractions, but patch tests with the water soluble fraction were negative in all. None of the other five patients taken as controls showed a positive patch test with any of the fractions.

With garlic, all seven patients allergic to garlic showed positive patch tests with all the fractions including the water soluble fraction, whereas all the six controls were negative.

Patch Tests With the Essential Oils of Onion and Garlic

Essential oil of onion was prepared by steam distillation of 100 gm Pusa-Red variety of onion bulbs at 100 C for four hours. The essential oil weighing 0.023 gm was dissolved in 1 ml of olive oil and used for patch tests on two patients allergic to onion and ten controls.

Essential oil of garlic was prepared in a similar manner from 100 gm of garlic bulbs and weighed 0.80 gm. It was also dissolved in 1 ml of olive oil and used for patch tests on five patients allergic to garlic and six controls.

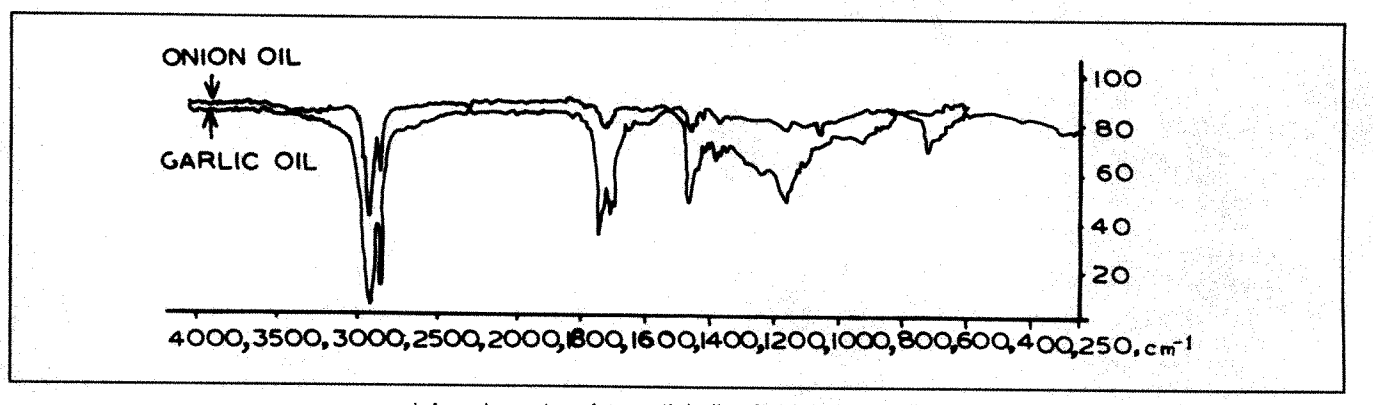
Patch tests with the essential oil of onion were positive in both the patients allergic to onion, and also in one out of ten controls. With the essential oil of garlic, all the five patients allergic to garlic showed positive patch tests, while all the six controls were negative.

Infrared Spectra of the Essential Oils of Onion and Garlic

The infrared spectrophotometer, was used to determine the infrared spectra of the essential oils of onion and garlic. The spectra were taken in carbon tetrachloride using 0.1 mm of sodium chloride cells. Solubility of the essential oil of onion was

Table 2.—Efficiency of Juice, Extract, and Solution Compared to Freshly Extracted Juice of Vegetables as Patch Test Material

Vegetable	No. of Patients Tested	No. of Patients Having Positive Patch Test						
		Juice		Extract		Solution		
		As Such	50% Concentration	As Such	50% Concentration	As Such	50% Concentration	Fresh Juice
Garlic	11	11	Nil	9	Nil	10	Nil	11
Onion	11	9	2	7	4	6	2	11
Tomato	5	3	1	3	1	Nil	Nil	5
Carrot	2	2	1	1	Nil	1	Nil	2



Infrared spectra of essential oils of onion and garlic.

very poor in carbon tetrachloride.

Essential oils of onion and garlic produced almost similar absorption bands; though the peaks produced by the essential oil of onion were much smaller as compared to those produced by garlic. The absorption bands were located at 3,100; 2,900; 1,743; 1,710; 1,468; 1,382; 1,245; 1,170; 922; and 720 cm^{-1} (Figure). The peaks at 3,100 and 1,710 corresponded to the straight chain acids, those at 1,743 and 1,170 to the esters, and those at 2,900, 1,468 and 720 to the methylene groups. The remaining bands were very weak. Allyl groups and sulfur bands were not demonstrable except in one out of two samples of essential oil of onion that showed a sulfur band.

COMMENT

Every year, 15 to 20 new patients with contact dermatitis due to vegetables are seen in our clinic. Many times this dermatological condition is discovered only during a routine examination, for it is often mistaken for knife cuts and ignored till it produces severe symptoms. Different vegetables have been incriminated by different workers[1-7,9]; however, our findings suggest that garlic and onion are the most common offenders. This is partly due to the fact that in north India, these two vegetables are used in almost every vegetarian or nonvegetarian dish, and are thus used every day throughout the year. In addition, the antigens in garlic and onion are also probably more potent sensitizers, because some other vegetables such as potato and tomato that are also frequently used, do not cause hypersensitivity with the same frequency. Nevertheless, in an individual patient, almost any vegetable can be responsible. Moreover, a patient may be sensitive to more than one vegetable. Therefore, it is necessary to test an individual patient with all the vegetables to which he or she is exposed. Otherwise, the contact dermatitis is likely to recur if the patient continues to be exposed to one or the other antigen.

It is difficult to ascertain the most ideal material for doing the patch tests. Freshly extracted juices of the vegetables are the most easily available materials, but some controls also showed positive patch tests. The prepared juices of the vegetables gave almost identical results in the patients, though a few patients were negative with the prepared juices. Among the controls, however more individuals gave positive reactions with the fresh juices than with the prepared juices. This difference could be attributed to the nonspecific irritant effect of the fresh juices, but since some controls were positive even with the diluted juices, it seems likely that some clinically normal individuals are having latent hypersensitivity but do not show clinical manifestations because they are not adequately exposed.

Tests with the diluted preparations of the juices showed that the degree of hypersensitivity in different patients varies; some patients gave a positive patch test with even 10% concentration of the juices, while others showed a negative test to even 50% concentration of the juice. With garlic juice, however, all the patients and the controls were negative when tested with a 50% concentration of the juice, while the juice used as such showed a high incidence of false-positive reactions. It is, therefore, considered necessary to reassess the situation using more purified components of garlic.

Attempts at preservation of the juice by lyophilization for patch tests at a later date proved unsuccessful because many patients showed a negative patch test with the solution when the patch test with the corresponding juice was positive. For routine use, therefore, it may be acceptable to use the juice of the vegetable without any dilution. Such a juice can be preserved for at least six months without any preservative by storing at 6 to 8 C. After the antigens are purified, it may be possible to use more specific materials for patch tests.

The antigens in onion and garlic are soluble in various fat solvents such as ether, acetone, and alcohol in addition to water as also reported by Burks[5] and Bleumink et al[9] and are present in the essential oils too. This information is useful for further purification and improvement of the patch test material. These antigens do not seem to be related to the sulfur-containing constituents, because none was found in the essential oils. Further studies will be necessary to characterize the antigenic substance.

Both these vegetables belong to the family Liliaceae to which tulips also belong. The essential oils extracted from onion and garlic produced similar spectra on infrared spectrophotometry, but other evidence suggests that the antigens in tulips, onion, and garlic responsible for contact dermatitis are probably different. Bleumink et al[9] and Bleumink and Nater[11] failed to observe cross-reactivity between onion, garlic, and tulip, and in our study also, out of 45 patients tested with both garlic and onion, only 25 patients were positive with both the vegetables. Nineteen patients showed a positive patch test with garlic only, and one patient was positive with onion only.

Bhag Chowdhary, PhD, Head, Division of Horticulture, Indian Agricultural Research Institute, New Delhi, supplied the standard samples of onion, tomato, and carrot, and M. L. Maheswari, PhD, Agro-chemical division of the same Institute, undertook infrared spectrophotometric analysis.

Microbial Flora of Atopic Dermatitis

Raza Aly, PhD; Howard I. Maibach, MD; Henry R. Shinefield, MD

• **The microbial flora of dermatitic skin, uninvolved skin, and the anterior nares of subjects with atopic eczema were investigated. The carriage rate of *Staphylococcus aureus* was 79% for the anterior nares, 76% for the uninvolved skin (normal skin), and 93% for lesions. The counts of *S aureus* were 7.5 × 10^4/sq cm in lesions and 7.1 × 10^3/sq cm on adjacent normal skin. *Staphylococcus aureus* was the predominant organism in the lesions and constituted 91% of the total aerobic bacterial flora. The coagulase-negative staphylococci were the second predominant organisms (9%). On normal skin, coagulase-negative staphylococci were the predominant organisms, constituting 63% of the total flora, followed by *S aureus* (30% of the bacterial flora). The micrococci counts were lower in the lesions (1.6 × 10^2/sq cm) and higher on normal skin (9.5 × 10^2/sq cm). Lipophilic diphtheroids were fewer on normal skin (6.7 × 10/sq cm), and there were none in the lesions. Fifty-eight percent of the strains belonged to group 3, and 38% were nontypeable. *Staphylococcus aureus* strains belonging to phage groups 2 and 4 were not detected.**

(*Arch Dermatol* 113:780-782, 1977)

Dermatitic skin provides favorable conditions for bacterial colonization and multiplication. The overgrowth of normal flora and the colonization of certain pathogenic microorganisms not only present a threat to the patient, but also to those who come in contact with him. High prevalence of *Staphylococcus aureus* in eczematous lesions have been reported[1-3]; *S aureus* was the most dominant species in the majority of the lesions.[2]

Previous studies have been concerned with the presence of *S aureus* or its dispersal in the hospital environment.[1,2] Documentation of the cutaneous flora in atopic dermatitis is incomplete, and further research needs to be done. This study was designed to investigate systematically (1) density of total aerobic microflora of inflamed and noninflamed skin, (2) composition of the normal flora of the noninvolved skin and the lesions, (3) comparison of nasal carriage of *S aureus* to that in noninflamed skin and lesions, (4) determination of the antibiotic resistance of *S aureus* strains and their phage pattern, and (5) incidence of major groups of bacteria on normal and dermatitic skin.

SUBJECTS AND METHODS

Thirty-nine patients ranging from 4 to 52 years of age (average, 19 years; median, 16 years) were studied. Patients receiving topical antibiotics or those producing systemic effects were not included. Some of the patients had received intermittent corticosteroid therapy before but not during the investigation. With the exception of two subjects, the lesions were chronic, lichenified, and nonexudative types. The sites for sampling bacteria were the anterior nares, the inflamed skin, and the adjacent noninflamed skin (about 5 to 8 cm away from the inflamed skin).

Sampling Methods

Samples were obtained by the detergent scrub technique.[4] An aluminum cylinder, 6.15 sq cm in area, was held to the skin, and the surface was rubbed with a teflon "policeman" in 1 ml of tyloxapol solution for one minute. Nasal flora were removed by using a calcium alginate swab. Samples (0.1 ml) from ten-fold dilution series were cultured on blood agar plates (5% difibrinated sheep RBC agar), trypticase soy agar with polyoxyethylene sorbitan mono-oleate to enhance the growth of lipophilic diphtheroids, eosin-methylene blue agar for Gram-negative, crystal violet agar for streptococci, and Sabouraud glucose agar for fungi. The culture plates were incubated aerobically at 35 C for 48 hours. The Sabouraud plates were incubated at room temperature. Colonial types were used for picking representative strains of different groups of bacteria. Gram strains were performed on selected colonies. Organisms were classified according to their response to biochemical tests and by their growth and/or morphologic features on selective differential media. *Staphylococcus aureus* strains were sent to the *Staphylococcus* Laboratory, Center for Disease Control for phage typing. The Kirby-Bauer method was used for determining antibiotic sensitivity of *S aureus* strains.

RESULTS

Qualitative Estimation of Microbial Flora

Subjects selected for this investigation were outpatients. The incidence of microorganisms on the anterior nares, normal skin, and lesions is shown in Table 1. The incidence of *S aureus* was high in all test sites: 93% in the lesions, 76% on the normal skin, and 79% in the nose. The occurrence of lipophilic diphtheroids was 2% on uninvolved skin, 20% in the nose, and none in the lesions. The incidence of micrococci was higher on the normal skin (25%) than in the lesions (13%). The carriage of coagulase-negative staphylococci was not substantially

Lipophilic diphtheroids	5.4×10^3	0	6.7×10
Bacillus sp	< 10	< 10	< 10
Gram-negative rods	< 10	< 10	< 10
Yeasts	0	0	< 10

different in uninvolved skin and lesions.

Semiquantitative Estimation of Microbial Flora

The mean density (39 subjects) of total aerobic flora was 8.2×10^4/sq cm in lesions and 2.4×10^3/sq cm on normal skin. Lesions had a mean density of 7.5×10^4 *S aureus* per square centimeter, compared with 7.1×10^3/sq cm on normal skin (Table 2). Pure *S aureus* (ie, no other organisms observed) with mean average counts of 2.6×10^5/sq cm was found in the lesions of seven subjects (18%); this ranged from 1.5×10^2 to 9.7×10^5/sq cm. The coagulase-negative staphylococci and micrococci were higher in density on normal skin than on the lesions. Lipophilic diphtheroids were not detected on the dermatitic skin; even on normal skin their density was extremely low (6.7 × 10/sq cm). *Staphylococcus aureus* was the predominant organism in the lesions and constituted 91% of the total aerobic bacterial flora. The coagulase-negative staphylococci were the second predominant organisms (9%). On normal skin, coagulase-negative staphylococci were the predominant organisms, constituting 63% of the total flora, followed by *S aureus* (30% of the total population).

Antibiogram of *S aureus*

The antibiotic resistance of 140 strains of *S aureus* was determined by using the paper disk (Baltimore Biological Laboratories) method and is shown in the following:

Antibiotic	Resistance, %
Penicillin (2 units)	63
Penicillin (10 units)	58
Cephalothin (30 μg)	0
Tetracycline (5 μg)	14
Erythromycin (2 μg)	20
Oxacillin (1 μg)	8
Novobiocin (5 μg)	2
Neomycin (5 μg)	1

Phage Types of *S aureus*

No phage group 2 or phage group 4 strains were detected in patients with atopic dermatitis. Thirty-eight percent of the strains belonged to group 3, and 38% were nontypeable. Thirteen percent of the strains were typeable with 29/52 only (group 1), and 12% were typeable with 94/96, for which no group is allotted. Different phage types were noted in the lesions, the noninflamed skin, and the anterior nares within the same subject.

COMMENT

The nasal carriage of *S aureus* in the normal population has a variable range of 10% to 45%[5,6]; while on the skin, with the exclusion of perineum, the occurrence is less than 10%.[7] In this study, the incidence of *S aureus* in patients with atopic dermatitis was not only higher in lesions (93%) and noninvolved skin (76%), but also on the anterior nares (79%). We have no specific explanation for the higher carriage of *S aureus* on the noninflamed skin and the anterior nares. Whether this is a continual dissemination from inflamed skin (a transient status) or actual colonization (a resident status) is difficult to answer. It has been postulated that this high density of *S aureus* may not only intensify previously existing lesions, but may play an important role in the practice of public health.[2] Patients with atopic dermatitis may present problems in the field of cross-infection, since they carry a large number of potentially pathogenic bacteria on dermatitic skin. Dispersion of *S aureus* from inflamed skin has been noted in hospital wards.[8,9] Wound infection associated with *S aureus* was traced to a resident physician who had atopic dermatitis.[2]

We did not see overt staphylococcal pyoderma or other clinical skin infection due to the overgrowth of *S aureus* in this population. Some patients complained of pruritus; we question if this may have been caused partly by staphylococcal toxins or other metabolites. Antibiotic treatment is sometimes helpful in impetiginized eczema.[10] The reduction in dermatitis may have been partly due to the elimination of *S aureus* by antibiotic treatments.

Huriez et al[11] demonstrated elevated antistreptolysin O titers in 23% of patients with eczema; we did not encounter hemolytic streptococci in our population. Hodes[12] reported the

spread of hemolytic streptococci over an entire ward from an infant with secondarily infected eczema.

Lipophilic diphtheroids are part of the normal cutaneous flora and are present most frequently on the skin. To our surprise, no lipophilic diphtheroids were detected in the lesions. Their incidence on normal skin was also minimal (2%). When the bacterial flora of the toe web was purposefully changed by the exaggerated use of antimicrobial soap, lipophilic diphtheroids were completely eliminated and were replaced with an overgrowth of Gram-negative rods.[13] Hyperkeratosis and maceration of the microbially altered toe webs were noted. It seems that the preponderance of lipophilic diphtheroids is indicative of normal healthy skin. A paucity of lipophilic diphtheroids was also noted on the normal skin adjacent to the lesions. Although nonlipophilics were encountered on normal skin and on the lesions, they constituted less than 1% of the total flora. An inverse relationship between diphtheroids and Gram-positive cocci has been noted for bacteria in the nose.[14]

Not only was the incidence of *S aureus* higher in the lesions of the patients with atopic eczema, but *S aureus* constituted 91% of the normal flora. On normal skin coagulase-negative staphylococci were the predominant organisms. The incidence and density of micrococci were also higher on normal skin than in the lesions. The occurrence of Gram-negative rods and *Candida albicans* was low in these patients. Our finding on the carriage of *S aureus* and their densities on the lesions and on normal skin is similar to those published by Leyden et al.[2]

We have no definite explanation for the high carriage of *S aureus* on the uninvolved skin and on the anterior nares. Whether this is dissemination from inflamed skin or actual inhabitation is an open question. It has been suggested that the uninvolved skin of patients with atopic dermatitis may be inherently favorable for *S aureus* colonization.[2] Clinically, healthy skin areas of patients with eczema are more suitable for the multiplication of *S aureus* than normal skin.[15]

The quantitative and qualitative estimations of normal flora, antibiotic sensitivity pattern, and phage types of *S aureus* have not been reported previously, to our knowledge. The finding that many strains of *S aureus* (38%) colonizing the skin of atopic patients belong to group 3 was unexpected, since most staphylococcal hospital epidemics in the 1950s through 1960s were of the types 52, 52A, 80/81 (group 1). The type 71 strains (group 2) have been associated with impetigo[16] and toxic epidermal necrolysis. No strain belonging to group 2 was detected.

It is perhaps biologically fortunate for these patients that they have been colonized by group 3 or nontypeable strains. Toxic epidermal necrolysis, bullous impetigo, recurrent furunculosis, and Ritter disease are most frequently caused by other than group 3 strains of *S aureus*. Is colonization with group 3 strains related to the patients' lack of contact with phage groups 1 and 2 (ie, a chance phenomena), or is there an ecologic reason for group 3 being favored over groups 1 and 2?

The fact that these patients have a reasonably high frequency of *S aureus* strains that are resistant to penicillin, erythromycin, and tetracycline must be viewed in perspective. At first thought, one might be tempted to suggest that these antibiotics might be contraindicated if frank cutaneous infection developed. Should the infection be serious, common sense would dictate this decision. In routine pyoderma (other than eczematous lesions), there are numerous examples of successful treatment with the antibiotics to which the probable pathogen were resistant.[17,18] It has been stated that this is because pyoderma was due to streptococci rather than *S aureus* seen in the culture.[19,20] At the moment the issue is subjudice; we suspect that there is a far from perfect correlation between antibiogram and clinical response in routine pyoderma.

This investigation was supported by research grant No. AI 1085604 from the National Institutes of Health.

The authors thank Charlene Shirley for her technical assistance and Dr H. Roth for his helpful advice.
